ABSTRACT

Results from field application of a strontium-90 beta particle attenuation method for measuring soil movement at the Pawnee Intensive Site are presented. Generally, it is concluded from 1970-1971 data that soil type and grazing treatment have not significantly influenced soil movement, although a trend of more soil-litter accumulation in the lightly grazed pasture as compared to the heavily grazed pasture was observed. Climatic factors associated with season are highly significant in their effect on soil movement with winter being a period of erosion and spring, fall, and summer generally showing accumulation. The yearly mean accumulation of 16 g/m²/month (.24 mm/year) is not significantly different from zero, indicating that on a short-term basis there is little net soil movement in the area of our plots.

INTRODUCTION

Implicit in understanding ecosystem function is knowledge pertaining to the abiotic elements of the system functioning as driving forces behind productivity. One such abiotic component, the soil, and in particular its erosional behavior, has been the objective of this research.

To investigate erosional behavior of soils at the Pawnee Intensive Site, a shortgrass plains ecosystem, a method involving strontium-90 beta particle attenuation was developed and employed. In lightly, moderately, and heavily summer grazed pastures 265 plots were established, and to date 1 year of data have been collected and analyzed.

METHODS

A detailed description of the beta particle attenuation method for measuring soil movement is presented in Alldredge and Whicker (1971). Therefore, only a brief resumé will be given here.

The basic principle of this method involves measurement of beta particles which penetrate the soil above a buried radioactive source. As soil or litter measured in milligrams per square centimeter is deposited over the source, a decreased count rate is measured using a portable Gieger-Mueller (GM) survey instrument. Removal of material results in an increased count rate.

Field application of this method allows detection of small soil fluctuations over a period of a few weeks. For example, a 45% change in count rate corresponds to a 1-mm change in soil depth which represents approximately 80 mg/cm² for Pawnee Site soils. As previously reported (Alldredge and Whicker, 1971), approximately 12% of the variance observed in data

could be attributed to variability in counting. When examining variance between plots from field data it was found that 2% of this variation was attributable to variance associated with the method. It should be emphasized that counting error can be reduced by increasing the duration of the count. When soil movement is minimal, error associated with methods becomes proportionately larger, and counting time may need to be increased.

Initially, a method involving fallout cesium-137 as a soil particle tag was proposed to investigate soil accumulation at the Pawnee Site. From data gathered from the literature and our own field and laboratory studies, it was concluded that cesium-137 was a good tag for Pawnee Site soil particles. Its downward movement in the soil profile is negligible, and the majority of the isotope is tightly bound to small soil particles. Its behavior is essentially that of the particle. Our initial intent was to determine soil accumulation by relating the depth at which the cesium occurred in the soil profile to the duration this isotope has been in the biosphere. Such an approach would give no measurement of erosion, but would indicate relative buildup rates in areas of soil accumulation. Problems such as obtaining a reliable depth sample in increments of 1 or 2 mm and of sufficient volume to enable detection of fallout cesium resulted when field application of this method was begun. To analyze the great number of samples necessary to describe soil accumulation on the Pawnee Site would require a prohibitive amount of counting time. The problems have not been resolved, and we have abandoned the cesium approach in favor of the beta particle attenuation method, which we feel will yield a more precise and reliable measure of soil movement for much less cost.

STUDY AREA

To obtain soil movement data for the Pawnee Site, the summer grazed pastures were selected as study areas. In the heavily grazed pasture (T10N, R66W, Sec. 23E) 100 plots were established. The lightly grazed pasture (Sec. 23W) was sampled with 45 plots, while the moderately grazed pasture (Sec. 15E), which contained twice as many soil types as the other pastures, contained 120 plots. The experimental design for this study, as well as the procedure used in locating transects and plots, has been reported previously (Alldredge and Whicker, 1970, 1971).

In order to properly compare soil movement data between pastures, it was necessary to determine relative surface area occupied by each soil type within the pastures. These proportions were used as weighting factors in data analysis. The results of this determination are presented in Table 1.

RESULTS AND DISCUSSION

Soil movement data summarized by season, grazing treatment, and soil type are presented in Tables 2 through 7. The data have been corrected for physical decay of the strontium-90 sources and thus differ slightly from data previously reported (Alldredge and Whicker, 1970). Data in Table 6 have been weighted according to relative surface area occupied by individual soil types. No correction has been applied for variable sample number between soil types and pastures. For a detailed discussion of the analysis performed on these data consult IBP Grassland Biome Statistical Services Rep. Proj. No. 40101 (Campion and Francis, 1971).

 $[\]frac{a}{N}$ No data were taken due to soil cracking with freezing and thawing and exposing radioactive sources.

Data were not taken for this pasture during the fall sampling period.
The winter sampling period extends from September through March for this grazing treatment.

Analysis of variance on data collected from September 1970 through August 1971 resulted in no significant differences (P < .10) in soil type erosional behavior as well as no effect of grazing treatments on soil movement. Significance (P < .05) was detected in the effect of climatic factors associated with season on soil movement with winter season illustrating a great loss for all soil types and pastures. Climatic data for the Pawnee Site and the work of Chepil, Siddoway, and Armbrust (1964) indicate that wind is the major agent of erosion on this study area.

The lack of significant differences in erosional behavior among soil types is not surprising as these soils are not highly different in composition (Franklin, 1969). The soils examined in this study belong to interpretive soil groups 1-4 used by Hyder et al. (1966) in a study which illustrated highly similar soil texture and subsoil permeability. Trends in the soil type analysis indicate that Ascalon soils generally accumulate more soil-litter material while the coarser Vona sandy loam shows a greater loss than do other soil types on a yearly basis. The Shingle-Renohill complex, which occupies the steeper slopes on the study area, shows considerable loss of material and has been previously speculated to be a readily erodable soil type (Franklin, 1969).

It might be suspected that grazing treatment would influence soil movement. Conclusions drawn by Hyder et al. (1966) state that vegetative composition is not significantly altered by grazing intensity on the study area, but that herbage yields were significantly different between heavy and light grazing treatments. As stated by Woodruff and Siddoway (1965), the type and amount of vegetation influences soil response to erosive winds.

Our data illustrate trends that indicate an influence of grazing treatments (Table 6) congruent with what one would intuitively suspect, but due to large variability in data from individual plots within soil types no significant differences (P < .10) were detectable. This variability is apparently real and not due to poor precision in methods as previously stated (Alldredge and Whicker, 1971).

From examination of preliminary weather data from the Pawnee Site, we conclude that a greater frequency of high velocity winds occur during the winter period. Such winds coupled with relatively low surface soil water indicated by low precipitation lead one to suspect that erosion would occur during the winter which, in fact, is indicated by our data. The current weather installations at the Pawnee Site should provide us with the data necessary to correlate soil movement with climatic factors such as wind.

Data presented in Table 7 indicate that aspect influences soil movement as has been observed with snow accumulation (Van Haveren and Galbraith, 1971). The difference in erosional behavior of the southwest and northeast exposures of the Ascalon soil type is highly significant (P < .05) with the northeast exposure illustrating more erosion and less accumulation than the southwest. A similar comparison of a Shingle soil series occurring on northwest and southeast exposures shows no significant differences in soil movement.

Data taken from plots in the ephemeral Lynn Lake and the topographic sinks (Table 7) indicate that while the erosion pavement-covered lake basin is losing soil, the topographic sinks covered with dense stands of buffalo grass (Buchloe dactyloides) are accumulating soil. Data from individual

plots at the edge of Lynn Lake where the buffalo grass community is established indicate that the lake may actually be filling in from its margins. This filling-in process, we speculate, proceeds with the advance of the grass community which serves to trap and hold soil particles. Data concerning the lake basin are tenuous due to the cracking of the high clay soil with freezing and thawing, which subsequently exposes many of the radioactive sources.

Examination of the mean accumulation of 16 g/m²/month (.24 mm/year) for Pawnee Site soil movement leads us to conclude that very little net movement is occurring in the area of our plots. This is possibly true for the entire Pawnee Site, but further consideration leads us to speculate that during the winter long-distance transport of soil-litter material may occur as a result of high velocity northwesterly winds. For the remainder of the year only local movement may occur. We have not adequately sampled the elevated terrain in the area as most of it lies outside the grazing treatment pastures. Local movement from ridgetops and high areas to lower lying regions, where the majority of our sampling is conducted, would result in the net accumulation we have measured. This speculation cannot, of course, be substantiated by data collected to date, but could be ascertained by other types of investigations such as sampling uplands and possibly using a soil particle tag such as iron-59 to trace soil movement patterns at specific sites.

In conjunction with our continued observation on plots, we have established 10 standard plots in different soil types at the Pawnee Site to examine the proposed problem of frost heaving of the strontium-90 source nails (Alldredge and Whicker, 1971). These plots are identical to the soil

movement plots with the exception that the strontium-90 sources are located above ground. If no alterations other than physical decay of the sources is observed in these plots, then we can assume that frost heaving has not influenced the data from the other field plots.

CONCLUSIONS

From a year of data recorded to date we observe the need for continued investigation to describe soil erosional behavior at the Pawnee Site. Observations are needed to further validate the method employed as well as to verify or refute trends observed in the first year's data. Continued readings to determine trend behavior would help elucidate long-term soil movement patterns. Generally, it can be stated from the 1970-1971 data that similarity exists in erosional behavior of soil types and that grazing treatment, while showing trends toward less accumulation in the heavily grazed pasture, does not significantly influence soil movement. Climatic factors associated with season have a significant effect on soil movement with the winter season showing soil erosion and the other seasons generally illustrating accumulation.

APPENDIX II

Soil Movement Data: Slopes

These data represent grams per square meter of soil fluctuations of plots at the Pawnee Intensive Site. They constitute Grassland Biome Data Set A2U709B. Data have been transformed from counts per minute to listed form. Format for this listing is as follows.

| Soil Series |
|--|
| Slope |
| Season |
| g/m ² /month soil fluctuation |
| |

Key:

| Soil Series | Slope |
|-------------|---------------|
| 1 = Ascalon | 1 = Southwest |
| 2 = Shingle | 2 = Northeast |
