Appendix I	31

ABSTRACT

Field data from investigations of aboveground primary production during the 1970 growing season at the Bridger Site are summarized and tabulated. Included are results from grazed and ungrazed areas, as well as two locations on which snow accumulation was artificially increased. Results from a sample of belowground biomass of plant material are also presented, as well as summary charts of air and soil temperatures through the growing season.

INTRODUCTION

The Bridger Site, located at 7800 feet MSL in the Bridger Mountains near Bozeman, Montana, is the highest and northernmost of the sites comprising the Comprehensive Network of the Grasslands Program of the US IBP. The site is described in IBP Technical Report No. 38. The site was selected in 1969 for inclusion in the Comprehensive Network. This report will describe the work conducted during that period and present a synthesis of the research data gathered during the 1970 growing season.

METHODS

Two basic treatments were used during the 1970 growing season, as prescribed by IBP Technical Report No. 35. These were: (i) an area which had long been excluded from grazing use, referred to as a "non-grazed area;" and (ii) an area which had received "light" grazing during the preceding (1969) growing season, referred to as a "grazed area." The site selected as the "non-grazed site" was one which had been under fence and excluded from grazing use since the 1930's. Total acreage involved was approximately 35 acres. An area directly adjoining the ungrazed site, supporting a very similar vegetational community, was selected as the grazed area. This area was fenced with 4 inch mesh fencing in early June, prior to grazing use. Two areas which appeared to be similar in their vegetational composition were selected within each treatment as replicates. Within each replicate, 15 ten m permanent transects were installed. Ten transects in each replicate were selected on a random basis for studies designed to determine vegetational productivity. The remaining five transects in each replicate were used for phenological

studies and soil-moisture determinations. In each of these five transects, "stacks" of soil moisture blocks were buried at 10 cm, 25 cm and 75 cm depths. Readings were made on a weekly basis during the growing season. Phenological measurements, including stage of development, leaf length, and culm length (where applicable), were gathered on the 21 species considered "most important" from a productivity standpoint.

Aboveground vegetational productivity measurements were initially taken June 23 on both the grazed and ungrazed areas and continued until September 1 on a biweekly basis. Ten 0.5 m^2 quadrats were clipped at crown level in each replicate at each sampling period. A "clip-rank" method of sampling was used. This involves: (i) ranking all species which contribute over 5% of the total productivity according to their relative individual productivities; (ii) clipping these species individually; and (iii) separating the remaining biomass into miscellaneous grasses, miscellaneous forbs, standing dead, and litter. Plant material was then dried for 24 hours at 65°C and weighed to the nearest gram. The results were then recorded on the appropriate forms. In addition, seventy additional 0.5 m^2 plots in each replicate were "ranked only" in the prescribed manner. All data were then submitted to the central laboratory at Colorado State University for mathematical analysis. In all cases, data were submitted within ten days after sampling. The data resulting from the vegetational sampling is summarized in this report.

Belowground biomass was estimated September 10 using soil cores. Ten cores, each 2 cm in diameter, were taken in each replicate to depths of 50 cm or bedrock. Each core was then separated into 10 cm intervals, with the exception of the upper 10 cm, which was subdivided into 5 cm increments.

The cores were then washed over a 32 mesh screen, oven dried at 65°C, weighed to the nearest 0.01 gram, washed, and the residue weighed. This data is also presented in this report.

In addition, standard weather bureau instruments were used to gather continuous data on air temperature, relative humidity, and soil temperatures at 10 cm and 50 cm. Weekly readings were taken on precipitation, wind and air maximum and minimum temperatures. All measurements were taken during the snow-free season only, which in 1970 involved the period from June 4 to September 11. A brief summary of some of these measurements is included in this report.

RESULTS

Aboveground productivity measurements were taken six times during the 1970 growing season. The sampling dates were June 22, July 8 and 20, August 3 and 17, and September 1. The resulting data is synthesized and presented on the following pages.

In addition to the grazing stress program conducted for the IBP, a study was also carried out at this site to determine the effects of increased snow-pack on the vegetational community. The snow depths involved were 4 ft and 9 ft, compared to the normal snow depth of 1½ to 2 ft.

This project, presently in its third year, is funded by the National Science Foundation under the direction of the author. Many of the graphs in this report include data from this project as well as data from the IBP study.
