INTRODUCTION

In this second part of the report on the wind field downstream from a two dimensional model hill the experimental data are presented in tabular form. For a first interpretation of the large quantity of data, the first part of the report should be consulted.

In the following paragraphs, the tables and the notations used for them are briefly explained.

Tables 1 to 8 : Velocity Distribution Data

The data tabulated in tables 1 to 6 are presented graphically in Figs. 15 to 32 in Pt. 1 of this report. The data tabulated in tables 7 and 8 pertain to velocity distributions in thermally stratified boundary layers downstream from a two dimensional hill. They were taken with the intention of finding out whether temperature gradients actually do have any effect on the highly turbulent flow downstream from the model hills, or whether all effects are obliterated by the large mixing. An analysis of these data has not yet been attempted.

In tables 1 to 8 the symbols used have the following significance: Hill models are described by the model shape and the ratio of height to base length. For example, a hill 1" x 4" will denote a hill with a height of 1" and a base of 4". P_{atm} is the atmospheric pressure at the beginning of an experiment. If the pressure did not change by more than 0.1 in. Hg. during a series of experiments then only one pressure is given on one page of a table.

The ambient velocity U_0 is measured at the horizontal distance $x = -36$ in. upstream from the hill, and at 3 ft. from the floor. The local ambient velocities are given by the asymptotic value of U for large vertical distances y from the wind tunnel floor. In Pt. 1, the ratio of the dynamic head corresponding to the local ambient velocity to the dynamic head based

on U_0 is shown in Figs. 15 to 32 to indicate possible pressure gradients which might have to be considered in a more refined analysis of the experimental data.

The horizontal distance from the crest of the model is denoted by x . The temperatures T of the ambient air were, in the small wind tunnel, measured by means of a mercury thermometer attached to one of the windows of the wind tunnel. In the large wind tunnel, the temperature was measured with a pneumatic bulb which is used for controlling the air temperature of the wind tunnel through the refrigeration system.

The vertical distance is denoted by y . Small errors in y of the order of $1/16"$ might have been possible due to non-linearity in the mechanism translating distance into the voltage of the $x - y$ plotter.

The pressure reading for each elevation y is given under the heading mm Hg. These are readings, corresponding to the output of the pressure transducer, averaged over the width of the trace on the $x - y$ plotter. The averaging was done by eye. From the pressures, the mean velocity was calculated by using the formula $U = 54\sqrt{\text{mm Hg}}$. The coefficient 54 used in this formula is exact for a temperature of 68°F and a density of the air of 0.002 slugs / ft^3 . No attempt was made to correct the velocity data for pressure or temperature, nor, for that matter, for turbulence effects.

In the last column, the $\overline{U^2}$ denotes the average square of the turbulent fluctuating velocity component in the direction of the flow. (i.e. in x - direction).

The cases of the different hill models and velocities as tabulated in Table 1 to 8 are listed in the table of contents.

Table 9: Vertical pressure distributions

For one hill model, wedge 2" x 2", the pressure in the vertical direction was measured in order to check the momentum balance near the hill. The procedure of checking the momentum balance is explained in 3.2 of Pt. 1 of this report. The data were taken with the static holes of the pilot-static tube. The pressure was referenced against the atmospheric pressure outside of the wind tunnel.

Table 10: Pressure distributions along the wall

Distances x are measured from the hill crest, h = model height. P = wall pressure, made non-dimensional by dividing through $1/2 \rho U_0^2$, where U_0 is the reference velocity measured at a distance of 3 feet upstream from the model.

Table 11: Pressure distributions about the models

The vertical distance y from the floor is made dimensionless by dividing through the model height. p_f is the pressure on the front, p_r the pressure on the rear side of the model, both are given in mm Hg.

Table 12: Summary of calculated data

Table 12 contains a summary of the parameters which were calculated from the experimental data tabulated in Table 1 to 11. Δh_a is again the pressure reading of the ambient air, obtained at a distance of 3 ft. upstream from the crest of the hill, and U_0 is the corresponding velocity, while P_{atm} . is the atmospheric pressure.

The drag coefficient C_D was calculated by the integral

$$C_D = \int_0^h \frac{p \sin \alpha - p_d \sin \alpha}{\frac{1}{2} \rho U_0^2} dy$$

In this expression, p is the pressure on the front of the model, p_d is the pressure on the back of the model, while h is the model height and y the vertical coordinate. The angle α is given by the slope of the model surface

at the elevation y . All pressures were measured in mm Hg and divided by Δh_a which, to a constant factor, gives $\frac{1}{2} \rho U_0^2$. The integration was performed graphically by plotting the pressures, $p \sin \alpha - p_d \sin \alpha$ which were calculated from the experimental data, against y , by connecting the pressure end points with a smooth curve, and determining the area under the curve with a planimeter.

The temperature T was measured, and the density ρ was determined according to the atmospheric pressure and the temperature from handbook values.

The displacement thickness δ^* was calculated from its definition:

$$\delta^* = \int_0^\delta \left(1 - \frac{U}{U_0} \right) dy$$

where U_0 is the asymptotic value of the velocity at large distances y at the given distance x , except in those cases where the velocity had a maximum rather than an asymptotic value. This occurred for boundary layers of small thickness and for wedge models (in the small wind tunnel). In these cases, the boundary layer thickness δ was defined as the distance from the floor, where the total head reached 99% of its asymptotic value at great heights above the floor.

The integration was performed by plotting $1 - \frac{U}{U_0}$ against y , fairing a smooth curve through the data points, and determining the area under the curve with a planimeter.

The momentum thickness θ was determined in the same manner from the defining equation

$$\theta = \int_0^\delta \frac{U}{U_0} \left(1 - \frac{U}{U_0} \right) dy$$

The form factor H denotes the ratio

$$H = \frac{\delta^*}{\theta}$$

U^* is the shear velocity. It was calculated by first determining the shear stress coefficient c_f from the equation of Ludwieg and Tillman which is given as Eq. 3-22 on p. 27 of Pt. 1 of this report. The shear velocity is then given by the relation

$$U^* = \sqrt{\frac{c_f}{2} U_0}$$

The quantity Θ denotes the contribution of the turbulent intensity to the momentum equation, i.e.

$$\Theta = \int_0^{\delta} \frac{\overline{U^2}}{U_0^2} dy$$

where $\overline{U^2}$ is the average value of the squared turbulent velocity component in the direction of flow. Again, the integral was determined graphically.

The distance σ is the width of the turbulent intensity "jet" (see p. 38 of Pt. 1).
