## ABSTRACT

### BETWEEN A BOULDER AND A HARD PLACE: AN ACTUALISTIC EXPERIMENT TO INFER THE IMPACT OF CAVE ROOF FALL ON LIMB BONES AND ITS IMPLICATIONS FOR THE ARCHAEOLOGICAL RECORD

Over 50 years of research has highlighted the important role hominins and carnivores play as agents of bone fragmentation. The work has largely been focused on differentiating the assemblages created by hominins from those modified by carnivores. Consequently, cave roof fall and other agents have received relatively little attention in this rich literature. Previous studies of cave roof fall have suggested it can modify assemblages in a manner that mimics hammerstone-on-anvil percussion of bones indicating the need for reliable criteria to distinguish between these two processes. Here, we conduct an actualistic experiment designed to simulate the effects of cave roof fall on bone assemblages.

Sixteen (n=16) bison tibiae were fractured in four experiments with drop heights of 4.6 and 7.6 meters and rock weights of 6.8 and 13.6 kilograms. To represent a hominin assemblage sixteen (n=16) tibiae were randomly selected from a hammerstone-on-anvil collection created by Robert Kaplan and stored at Colorado State University. Bone surface modifications (BSM) counts that include pits, notches, grooves, and striations were created for both groups. Additionally, notch measurement ratios, Incipient notch counts, fragment counts, general fragment size frequency distributions, epiphyseal fragment measurements, percentages of fragments with BSMs, and presence/absence of stress relief traces (hackle marks and ribs) were collected from both groups.

Results suggest that flake count, pit count and the percentage of fragments with pits and/or grooves are the variables which are different between cave roof fall and hammerstone-on-anvil percussion. These variables are significantly different between the two assemblages; however, they are not applicable to the archaeological record. This is because the traces that these variables were built upon are not distinguishable between the two actors. This qualitative approach to address the equifinality between cave roof fall and hammerstone-on-anvil percussion has failed to provide any valuable insights.

## ACKNOWLEDGEMENTS

Firstly, I am indebted to my committee members for their support and feedback for this thesis. I would like to thank Dr. Mica Glantz for providing me with a sound board, feedback, and encouragement. The same goes for Dr. Michael Pante, who provided encouragement, feedback and his taphonomic expertise. Finally, I would like to thank Dr. Ann Hess for her feedback and statistical guidance. Additionally, I would like to acknowledge Dr. Andrew Du for providing additional statistical guidance and insight. Finally, I would like to thank the College of Liberal Arts and the Department of Anthropology and Geography for providing me a portion of funding for the experiment and classes needed to complete my Master's Degree.

Secondly, I would like to thank my family for supporting me and encouraging me to pursue a Master's Degree. This thesis would not have been possible without their support.

Next, I would like to thank my partner, Denise Frazier, and her family. The actualistic experiment at the heart of this thesis would not have been possible without Denise helping me set up the pulley system, break the bones, endure the bone boiling process, and endless editing. As well as her family for encouraging both of us.

Lastly, I would like to thank my cohort for their comradery and support. Many of us depended on the Friday pitchers at Avo's to keep some sanity. Special mention goes to Robert "Bobby" Kaplan for creating the hammerstone-on-anvil sample used in this thesis.

I am grateful for everyone that has helped and supported me on this journey. This is dedicated to you!

## CHAPTER I: INTRODUCTION

Fractured bones are a common component of many archaeological assemblages associated with hominins from the Pliocene, Pleistocene, and Holocene records (Blumenschine, 1995; Bunn et al., 1986; Morlan, 1994). Bone fracture is defined as the breakage of the diaphyseal cortical surface into the medullary cavity of the bone, creating two large bone fragments along with smaller fragments (Johnson, 1985). While most archaeological sites preserve fractured bone, the process of fracturing is not exclusively an anthropogenic or hominin phenomenon (Gifford-Gonzalez, 2018c; R. L. Lyman, 1984; Myers et al., 1980; Oliver, 1989). Carnivore made assemblages of fractured bone have been created in laboratory settings and have been recovered from time periods that predate hominins. (Blumenschine, 1995; Coil et al., 2017; Haynes, 1983; Myers et al., 1980; White et al., 1991). Herbivores can induce bone fragmentation through trampling suggesting that bone fragmentation is not a carnivore or hominin exclusive phenomenon. Bone fragmentation is not just a biotic phenomenon but can also have abiotic causes. Abiotic vectors of fragmentation include but are not limited to soil compaction, diagenetic processes, weathering, impact following free fall, and roof fall (Behrensmeyer, 1978; Denys, 2002; R. L. Lyman, 1984; Oliver, 1989; Villa & Mahieu, 1991).

Research into causes of bone fragmentation has largely favored hominin and carnivores as the main accumulators of broken bone assemblages (Binford, 1981c; Bunn et al., 1986; Capaldo & Blumenschine, 1994; Coil et al., 2017; Haynes, 1983; Johnson, 1985). This is understandable because both hominins and carnivores are active accumulators, meaning the accumulation is done with intent. This intent is nutritional, with each feeding episode expanding the assemblage. By studying these accumulations, anthropologists can piece together an understanding of hominin feeding behavior by separating hominin generated assemblages from

carnivores created assemblages (Binford, 1981d; Blumenschine, 1995; Blumenschine & Selvaggio, 1988; Capaldo & Blumenschine, 1994; Gifford-Gonzalez, 1991; Johnson, 1985).

Feeding behavior can be used as a proxy for hominin habitation and presence at a site. Further research into more complex hominin behaviors can be conducted once a hominin presence has been firmly established.

The focus on biotic accumulators has produced a substantial collection of literature, dwarfing the sizable literature on abiotic causes of bone fragmentation (Andrews & Whybrow, 2005; Kos, 2003; Mann & Monge, 2006; Oliver, 1989). This gap in research is detrimental to the narratives that are created about hominin feeding behavior and more complex behaviors. This is because while abiotic causes of bone fragmentation are not intentional, they can still contribute to the understanding of hominin feeding behavior and more complex behaviors derived from established hominin sites (Binford, 1981a; Griggo et al., 2019; Haynes, 2015; R. L. Lyman, 1984; Oliver, 1989; Olsen & Shipman, 1988; Trinkaus, 1985). Hominin involvement as an accumulator of bones at a site can be overturned or diminished if abiotic accumulators are shown to have played a part in the accumulation seen at the site (Binford, 1981a; Mann & Monge, 2006; Oliver, 1989; Trinkaus, 1985). Emil Bächler's interpretation of the Drachenlock assemblage, and the overturn of this interpretation by Bjorn Kurten is an example of where hominin involvement was overturned.

The cave bear cult has its origins in Bächler's interpretation of cave bear remains at Drachenlock cave (Switzerland, Upper Paleolithic) (Chase, 1987; Pacher & Rabeder, 2016). Bächler's excavations unearthed a cave bear faunal assemblage, which included a cave bear limb bone thrust through the eye socket of a cave bear skull, and four bear skulls encased in a crypt (Kurtén, 1995). Hominin tools or other hominin traces were not found among the cave bear

assemblage at Drachenlock cave (Wunn, 2001). He interpreted these cave bear anomalies as evidence that Neanderthals manipulated the bones and skull as part of a religious rite (Chase, 1987). This interpretation created and popularized the idea of the cave bear cult (Kurtén, 1995). Later this interpretation was challenged and overturned on the basis that hominin created tools or other traces of hominin habitation were not associated with the cave bear assemblage (Wunn, 2001). Kurten (1995) building on the work of others suggested that a combination of cave bear trampling and geologic activity through cave roof fall are responsible for manipulating the bones to their discovered positions.

While the “Cave Bear Cult” is an example where hominin action was overturned, the highly fragmented Neandertal remains and faunal assemblage from Krapina Cave is still poorly understood. The Krapina rock shelter (Croatia, 130 kya) is one of the oldest and largest caches of Neanderthal remains ever discovered (Gorjanović-Kramberger, 1906). The fact that the collection is also highly fragmented has been the source of speculation for multiple generations of paleoanthropologists. Some of the literature credits Neanderthals as the accumulators through cannibalistic behaviors (Ullrich, 2005; Villa, 1992). Others suggest cave roof fall as the primary agent of bone fragmentation at Krapina (Mann & Monge, 2006; Trinkaus, 1985). If cave roof fall can be distinguished from hammerstone-on-anvil percussion through actualistic experiments, this knowledge can be applied to solve the equifinality between the actors and end the debate over the culpable actor at Krapina and other sites with uncertain actor involvement.

## **1.1 Research Question and Theoretical Framework**

The research question that is at the center of this experiment is whether the taphonomic signature of roof fall is different from the taphonomic signature of hammerstone-on-anvil percussion. The reasoning behind this question is the blind spot in the taphonomic literature

concerning cave roof fall. This is seen in the prevalence of cave roof fall events described in archaeological sites, however sparse research has been done to characterize the taphonomic pattern left by cave roof fall on bone assemblages. This lack of research is seen in the sparse actualistic studies and descriptions of cave roof fall in the taphonomic literature (Dixon, 1984; Karr & Outram, 2012a; Oliver, 1989).

To investigate if the taphonomic signature of cave roof fall is different from the taphonomic signature of hammerstone-on-anvil percussion the following hypotheses were developed:

**H<sub>0</sub>:** All variables collected indicate that the taphonomic pattern of cave roof fall is not different from that of hammerstone-on-anvil percussion.

The null hypothesis (H<sub>0</sub>) will be considered if all the variables collected prove not to be significant in differentiating between cave roof fall and hammerstone-on-anvil percussion.

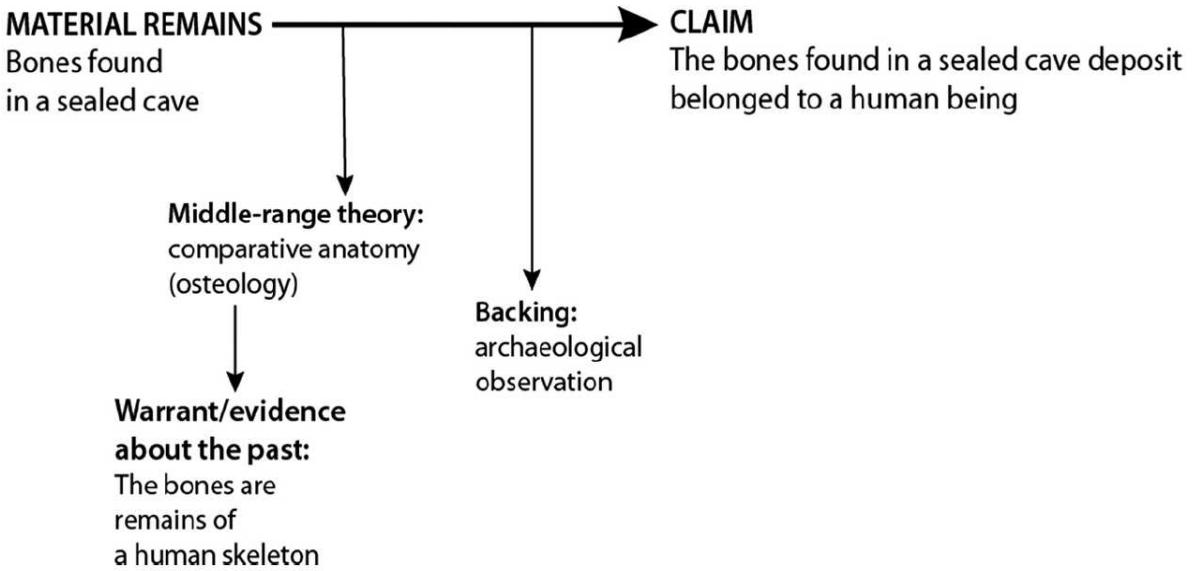

**H<sub>1</sub>:** All variables collected are indicative of a difference between cave roof fall and hammerstone-on-anvil percussion.

The condition under which the first alternative hypothesis (H<sub>1</sub>) will become viable is if all the variables collected point towards a difference between the taphonomic pattern of cave roof fall from hammerstone-on-anvil percussion.

**H<sub>2</sub>:** Some of the variables collected are different in the taphonomic patterns of cave roof fall compared to hammerstone-on-anvil percussion.

This second alternative hypothesis (H<sub>2</sub>) will be evident if one or more variables but not all variables, are different between the taphonomic pattern of cave roof fall and hammerstone-on-anvil percussion.

It is the aim of this thesis to utilize an actualistic experiment to infer the taphonomic signature of cave roof fall. This is achieved by simulating cave roof fall using various weights and heights on a sample of bison bones. After the experiment was executed, multiple variables were collected from the broken bones and compared to the same variables collected from sample of bones that were primarily modified by hammerstone-on-anvil percussion in a laboratory setting. If no variables stand out as being significantly different between the two actors, then the equifinality remains between the two actors. An equifinality is when two actors are indistinguishable because they leave the same trace pattern (R. Lyman, 1987). This means that other avenues must be used to solve the overlap between the two actors. If some variables do prove to be significant different between the two actors, then the equifinality between the two actors can be further explored. This means the variables that are found significant could be applied to the archaeological record to refine the hominin taphonomic signature by removing any uncertainties brought up by cave roof fall.

*Figure 1 An illustration of the processes that encompass middle-range theory and middle-range research. From “Warrants, Middle-Range Theories, and Inferential Scaffolding in Archaeological Interpretation”, by K. Kokkov, 2019, Perspectives on Science, 27(2), p. 183.*

The theoretical framework that allows this experiment to be valid is primarily middle-range theory and actualistic studies. Binford (1981b) developed middle-range theory to verify traces made in the past by recreating the traces in the present as seen in Figure 1. As he points out an archaeological assemblage is static and devoid of energy. This means that the taphonomic history of the assemblage, which includes all actors that partook in the creation of the assemblage, is all superimposed on the assemblage eliminating time and causal relationships, leaving only traces. In order to correctly link the trace with the actor Binford (1981b) proposes actualistic experiments as a bridge between the past and the present. These experiments seek to recreate the traces seen in the past by mimicking a suspected actor.

Actualistic experiments in turn depend on the assumption of uniformitarianism, which states that the processes today are the same as processes in the past. Actualistic experiments link traces in the present to traces in the past through relational analogies. The links created by actualistic experiments in turn can be applied through inductive reasoning to the archaeological

record to verify that traces seen at a site can be linked to an actor as seen in Figure 1. By successfully applying the findings of an actualistic study to an archaeological assemblage the taphonomic history of the assemblage can be better understood enabling archaeologists to link traces with actors. Once all traces have been securely linked to their respective actors, the actors of interest can be refined and studied.

## **1.2 Summary of Chapters**

Following this chapter will be Chapter II the Background chapter that will explore and define the concepts necessary to contextualize the research questions presented in this chapter. Chapter III Materials and Methods will detail the materials that were used in this actualistic experiment, and the methodology to carry out the experiment, gather data, and analyze the data. Chapter IV, the Results chapter will present the findings of this experiment and any variables that were found to be significant in differentiating between cave roof fall and hammerstone-on-anvil percussion. Chapter V is the Discussion chapter in which the driving forces behind the significant variable will be explored, and the insignificant variables will be discussed, and any untested variables will be explained. The final chapter will be Chapter VI Conclusion which will summarize the findings and provide some directions for future research and the expansion of this research.

## CHAPTER II: BACKGROUND

### 2.1 Taphonomy and Paleoanthropology

Taphonomy can be described as the science of death and fossilization (Gifford, 1981). It was defined by Ivan Efremov who sought to investigate and decipher the fossilization process (Efremov, 1940). Taphonomy borrows concepts from geology, paleontology, and ecology (Gifford, 1981). Taphonomy as a science can be divided into three parts, necrology, biostratinomy, and diagenesis. These parts together document an organism's journey from death to discovery (Grupe & Harbeck, 2014). Necrology explores the death of an organism, which could be from predation or other environmental factors, such as mass die-offs during droughts (Grupe & Harbeck, 2014). Biostratinomy is the interaction between the carcass and the biosphere until burial occurs, which includes interactions with scavengers, disarticulation, and transport by biotic and abiotic actors (Gifford, 1981). Lastly, if the assemblage is buried it becomes subject to diagenetic processes, like microbial attack and calcium leaching which are examples of biotic and abiotic actors that affect the assemblage until its discovery (Grupe & Harbeck, 2014).

The principles of taphonomy have wide applications across disciplines interested in ancient biota (Gifford, 1981). The addition of taphonomy was an important milestone in the maturation of paleoanthropology as a discipline because it employs faunal remains as one of the criteria to separate a hominin signature from the “white noise” present at sites. Properly attributing faunal remains as hominin altered is crucial in correctly interpreting hominin behavior (Gifford-Gonzalez, 1991). The incorrect assessment of altered faunal remains can lead to false interpretations of hominin behavior. These incorrect interpretations can lead to an incorrect understanding of hominin behavior as seen in the Cave Bear Cult inferred from the Drachenlock cave in Switzerland by Emil Bächler (Kurtén, 1995; Pacher & Rabeder, 2016). Bächler jumped

to the conclusion that Neanderthals were worshiping cave bears because of what he interpreted as crypts where cave bear skulls were supposedly stashed by Neanderthals. After this site was reevaluated using taphonomy it was found that the crypts were created by natural forces (Gargett et al., 1989). Taphonomy is a vital tool for interpretation in paleoanthropology because it helps accurately decipher the actor responsible for producing a site. Taphonomy is necessary for interpreting site remains and must be used along-side a theoretical framework for well-rounded interpretations (Gifford-Gonzalez, 1991). Taphonomy and its accompanying theoretical application, middle-range research, need to work in tandem to provide a proper site interoperation. Taphonomy is the practical part of site interpretation, where trace patterns are recorded. Middle-range research in turn connects and verifies the trace patterns recorded at a site with the responsible actors through experimentation in the present. Together taphonomy and middle-range research provide a framework to properly interpret the taphonomic history of a site.

Similarly to how paleoanthropology imported taphonomy from paleontology to understand the actors present in an assemblage, middle range theory was appropriated from archaeology to provide the theoretical framework for taphonomy (Binford, 1981b; Gifford, 1981). Middle-range theory links the past with the present by validating actors responsible for assemblages in the past through actualistic experiments in the present (Binford, 1981b). The linkage of the past and present is possible through the assumption of uniformitarianism. Uniformitarianism was developed by James Hutton as one of the pillars of geology. It states that processes in the past and present are the same and operate the same way (Hutton, 1788). In a paleoanthropological sense, this means that processes in the past are assumed to have left the same kind of pattern as they do in the present (Binford, 1981b). An example of this would be the traces left on bone by hammerstone-on-anvil percussion in archaeological sites and the

hammerstone-on-anvil percussion traces generated during an experiment, both are assumed to leave the same trace (Binford, 1981b). Uniformitarianism and middle-range theory provides the link between the past and the present and thus traces left by processes can be assumed as constant, the processes themselves just need to be isolated which can be done through actualistic experiments (Gifford-Gonzalez, 1991).

The necessity of actualistic experiments is illustrated by Binford (1981b), when he describes archaeological assemblages as inert, with indistinguishable patterns from all processes that contributed to the assemblage. Linking patterns to processes solely based on the archaeological sites leads to circular reasoning, which then gets applied to other sites, and eventually metastasizes into myths. (Binford, 1981a). An example of this is the case of the Guattari Cave (Italy, 52 kya) skull (Piperno & Giacobini, 1990). The Neanderthal skull was recovered from an faunal assemblage on the cave floor by Alberto Claro Blanc in 1939 (White et al., 1991). Blanc noticed that the base of the Neanderthal skull was missing, which he interpreted as headhunting and skull worship behavior (Wunn, 2000). This interpretation was based on traces interpreted as cut marks left on the skull and on the Neanderthal's skull superficial similarity to a museum collection of head hunter modified skulls (White et al., 1991). The association of two concepts based on superficial similarities is called a formal analogy (Gifford-Gonzalez, 1991). Following Blanc's interpretation Neanderthals were thought to possess a rudimentary skull cult and engage in head hunting (Wunn, 2000). Later the skull was reevaluated through data gathered from actualistic experiments which overturned Blanc's interpretation. The "cut marks" were properly identified as tooth marks and the damage at the base of the skull was attributed to a hyena accessing the brain cavity (White et al., 1991). Actualistic experiments are modern-day experiments that seek to recreate the pattern of one

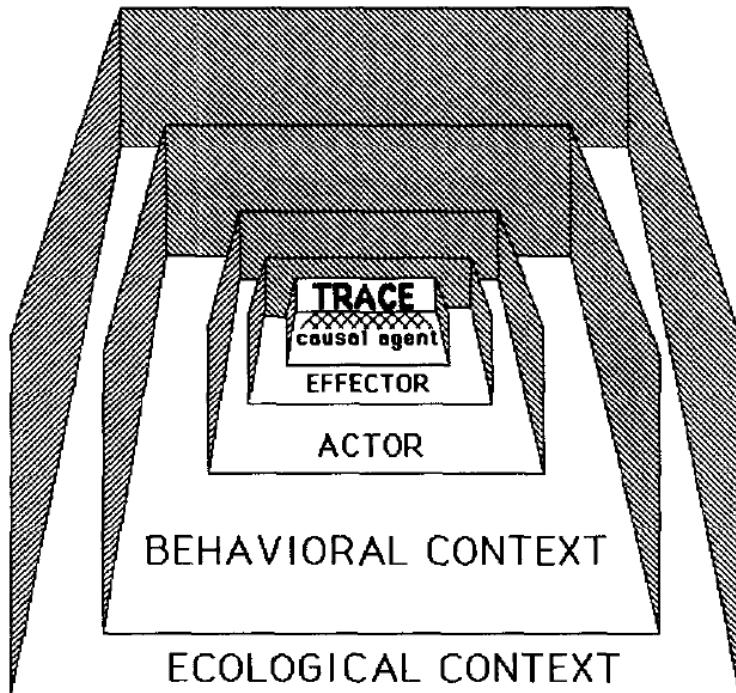

process seen in the past. Actualistic experiments allow control to be exerted on one process so that the pattern and process can be unequivocally associated (Binford, 1981b). Once the actualistic experiment is carried out and a reference collection created, the pattern and process have a relational analogy (Binford, 1981a; Blumenshine, 1995). This relationship can then be applied to the archaeological record facilitating the identification of a responsible actor in the assemblage (Binford, 1981b). While middle-range theory does have other uses for this thesis its main use is to facilitate actor differentiation. Through actualistic experiments and uniformitarianism, middle-range theory breaks the cycle of mythmaking and provides the means to analyze an archaeological site with an objective methodology (Binford, 1981a). While middle-range theory and uniformitarianism provide the theoretical backbone for taphonomy, relational analogies provide the connective tissue for a taphonomic analysis (Gifford-Gonzalez, 1991).

Relational analogies are the means through which middle-range research can be applied to a taphonomic interpretation of an archaeological site. Relational analogies link two concepts through a causal link, where process A produces only B (Gifford-Gonzalez, 1991). For example, using a stone tool to strip flesh from bone will leave cut marks on the bone. The two concepts, cut marks on bone and cutting meat off bone with a stone tool are linked through a relational analogy where cutting meat from a bone with a stone tool produces cut marks on bone.

Relational analogies are at the core of actualistic studies, where traces created in the present can be causally linked to actors because the causal interaction between the actor and the trace is observed. The relational analogies created in the present can then be exported into the past through the assumption of uniformitarianism. Much the same way that uniformitarianism assumes that processes in the past are the same as processes in the present, relation analogies can also be applied from the present to the past. To invoke the earlier example, if cut marks can be

causally linked to butchering with stone tool in the present, then this link between the two can be assumed to have happened in the past as well. Hominins using a stone tool to butcher a carcass in the past would leave similar traces to those produced during an actualistic experiment in the present (Binford, 1981b). This assumption can be made because in both instances a cutting motion is used to strip the meat off the bone using a stone tool. Thus, the present and the past can be connected through relationships created during actualistic experiments in the present and transferred to the past through relational analogies and the assumption of uniformitarianism.

Relational analogies are used in middle-range theory and taphonomy to act as bridges of inference between a known concept and an inferred one (Gifford, 1981). Gifford-Gonzalez (1991) creating a nested hierarchy of necessary steps as seen in Figure 2 to help build a proper interpretation of an archaeological site. This is necessary because as Binford (1981b) pointed out an archaeological site is an inert entity, with all forces and processes involved in creating the site already spent and gone. What is left is an amalgamation of signatures and traces without the actor and effector present. To prevent misinterpretations through formal analogies, the most basic and empirical evidence must be considered first (Binford, 1981a).

*Figure 2 Nestled hierarchy of steps necessary to build a proper network of inferences between steps. From “Bones Are Not Enough: Analogous, Knowledge, and Interpretive Strategies in Zooarchaeology” by D. Gifford-Gonzalez, 1991, *Journal of Anthropological Archaeology*, 10(3), p. 229. Traces are the outcome of an effector interacting with a bone (Gifford-Gonzalez, 1991).

These traces can be cutmarks, percussion marks, or chop marks associated with hominins (Fisher, 1995) or toothmarks, tooth furrows, or tooth pits associated with carnivores (Fisher, 1995). Abrasions and defoliation are associated with various abiotic processes (Fisher, 1995).

Collectively traces left on bone can be referred to as bone surface modification (BSMs). Through the interaction of the effector with the bone, traces are imprinted on the bone, and as long as those traces remain, they are the most empirical and tangible evidence, and are at the center of the nested hierarchy as seen in Figure 2 (Behrensmeyer, 1978; Gifford-Gonzalez, 1991). Once these traces are identified they can be linked to an actor through a causal agent (Gifford-Gonzalez, 1991).

From traces, the next step is the identification of the causal agent which addresses the processes of how the traces were created (Gifford-Gonzalez, 1991). For example, a cutmark and a toothmark are created through slightly different means, with one involving an interaction between a lithic tool and bone, while the other is an interaction between two organic entities, which ultimately will leave different traces (Shipman, 1981). These causal agents interact with the bone using different types of force. For example, cutmarks are left on bone following the application of force in a scraping motion, while percussion marks are left following the application of energy during a dynamic loading episode (Johnson, 1985). For this thesis, only loading types will be explored since it is the only kind of force relevant to the research question.

Loading can be divided into two categories, dynamic and static (Johnson, 1985). The difference between the two is in the way that force is applied. Dynamic loading is characterized by a concentrated delivery of force to a small surface area (Johnson, 1985). In terms of lithics, dynamic loading is employed during percussion flaking (Johnson, 1985). Similarly dynamic loading is associated with hominins and the use of hammerstone-on-anvil percussion to fracture bones (Capaldo & Blumenschine, 1994). Static loading is the application of constant pressure over a surface area and is seen during pressure flaking in lithics (Johnson, 1985). Within paleoanthropology, static loading has been associated with carnivore interaction with bones (Capaldo & Blumenschine, 1994). Carnivore teeth eventually crack bones through structural fatigue by applying constant localized pressure on the diaphysis of the bone (Johnson, 1985). Dynamic and static loading are the two main causal agents that are involved in bone fracture (Johnson, 1985).

Traces and causal agents describe the way that an effector interacts with bone, which leads to the next inference step, the effector (Gifford-Gonzalez, 1991). While the causal agent

describes the physics behind the creation of traces, the effector refers to the actual object that interacts with bone and creates the trace (Gifford-Gonzalez, 2018c). An effector can be connected to a biotic process as seen with carnivore jaws and teeth, hammerstone-on-anvil percussion used by hominins, grains of sand interacting with bone during trampling by herbivores, or related to abiotic processes, as shown by a rock hitting bone during a roof fall event, or sediment pressure as part of deposition among others (Capaldo & Blumenschine, 1994; Oliver, 1989; Olsen & Shipman, 1988). The effector is the catalyst through which the causal agent interacts with bone.

The actor is a conceptual level above the effector (Figure 2) and requires an inferential bridge to associate it with the effector (Gifford-Gonzalez, 1991). The actor is the individual or process that employed the effector (Gifford-Gonzalez, 2018a). This relationship is easy to understand in a biotic context, as a hominin actor employs the hammerstone (effector) to fracture the shaft of the bone leaving a trace, or that a carnivore actor employs its jaws and teeth as effectors to fracture the diaphysis of a bone leaving a trace (Gifford-Gonzalez, 1991; Johnson, 1985). These connections are clear to interpret because they are intentional, however unintentional employment of an effector by an actor is also possible. An example of this is trampling done by an animal that causes the grains of sand to abrade the diaphysis of the bone, or a roof fall event where a falling piece of bedrock fractures a bone on the cave floor. These are both events without any intention or purpose (Fisher, 1995). Actors link traces, causal agent and, effectors to a behavioral and ecological context. (Gifford-Gonzalez, 1991).

The behavioral context is the penultimate level in the hierarchy as seen in Figure 2 and describes why actors engage in certain behaviors and is informed by all lower levels (Gifford-Gonzalez, 1991). With biotic actors the behavioral context might involve nutrient acquisition or

tool production. The behavioral context can also help to describe assemblage formation as there is an intention behind the bone accumulation (Gifford-Gonzalez, 1991). Although abiotic actors do not process bones for a purpose, they can still provide important criteria used to identify intentionally processed bones (Oliver, 1989; Olsen & Shipman, 1988). From the reconstruction of the behavioral context, it is possible to infer why and how the assemblage was created.

At the top of the hierarchy as seen in Figure 2 is the ecological context (Gifford-Gonzalez, 1991). The ecological context is dependent on properly constructed inference connections between the lower steps (Gifford-Gonzalez, 2018a). The purpose of the ecological context is to determine a biotic actor's role within the surrounding environment (Gifford-Gonzalez, 2018a). This can involve the role of hominins as hunters and/or scavengers, the carnivore guild present in area, or even the kind of vegetation cover present at a site (Blumenshine et al., 1994). The ecological context can also be extended to abiotic actors. Fast deposition of soil over bones leading to sedimentary overburden action on bones could be indicative of a wet environment. Likewise, rapid fluctuations in climate can lead to intensive weathering of bedrock on a cave roof which would promote the frequency of roof fall episodes within a given period, increasing the likelihood of an interaction between roof fall debris and bones, if bones are present in the cave (Mann & Monge, 2006). As the final step of the hierarchy, the ecological context is the most susceptible to incorrect interpretation (Gifford-Gonzalez, 1991). This vulnerability can be seen in the ongoing debate on the role of hominins as hunters or scavengers(Blumenshine, 1995; Gifford-Gonzalez, 2018d).

Lastly, equifinality is the final core concept within bone assemblage analysis. Lyman (1987) defines equifinality as two different processes creating the same pattern. In this context equifinality would be two actors creating the same trace making it impossible to determine the

responsible actor (Gifford-Gonzalez, 1991). This, for example, could be carnivores gnawing and hominin percussion producing spiral fractures, or roof fall and hominin percussion leaving similar traces on modified bone (Johnson, 1985; Oliver, 1989). Though some equifinalities can be solved by using other variables, others cannot be solved without external means (Capaldo & Blumenschine, 1994; Oliver, 1989). Actualistic experiments are the most effective way to determine if there are other ways to differentiate the correct actor or if it truly is an equifinality (Binford, 1981b; Karr & Outram, 2012a)

Poor inferences can compromise the information that is gained from studying traces and leads to faulty conclusions. (Binford, 1981a; Gifford-Gonzalez, 1991). A famous example of poor site interpretations is Raymond Dart's proposal of the osteodontokeratic industry unearth at Makapansgat Cave (South Africa, 3-2.6 mya, Herries et al., 2013). Dart began excavations at Makapansgat following his chance encounter with the Taung child (*Australopithecus africanus*) fossil excavated at Taung quarry in South Africa (Derricourt, 2009). Makaganscat yielded a large fragmented faunal assemblage intermixed with hominin bones that was dominated by spiral fractures (Langdon, 2016). Dart interpreted the presence of spirally fractured limb bones as proof that the assemblage was created by hominins based on the idea that hominins were the only species able to produce spiral fractures through the "crack and twist" technique (Brain, 1983). Dart further interpreted the fractured hominin limb bones as signs of violence and cannibalism perpetrated by the local hominins against their own kind by using animal bones as a pre-lithic industry called osteodontokeratic industry (Langdon, 2016). From there on Dart weaved a "myth" narrative that our ancestors were hyper-violent apes that aggressively hunted and engaged in violence and cannibalism to explain the horrors and brutality seen throughout human history and showcased in World War 2, thus creating the "Killer Ape Hypothesis" (Binford,

1981a; Kover, 2017). This interpretation was later challenged and overturned by Charles K. Brain, who pointed out that spiral fractures can be created by carnivores as well, falsifying Dart's osteodentokeratic hypothesis and providing evidence of carnivore involvement by matching punctures on an australopithecine to the jaws of a carnivore (Brain, 1983; Dart, 1957).

## 2.2 Traces and Taphonomic Site Interpretation

Middle-range theory and research integrated smoothly within taphonomy in the second half of the 20<sup>th</sup> century. This integration enabled the revision of previously faulty interpretations by questioning the degree of human involvement and offering more grounded explanations. As the taphonomic history was revised at some sites, African sites became of interest. This interest was grounded in the pursuit to understand when hominins began to modify and exploit carcasses. This led to an increase in middle-range research by paleoanthropologists to understand the taphonomic signature left by hominins, separate it from the signature of other actors and refine it, to gain a better understanding of hominin feeding behavior.

Dart (1957) first proposed fracture pattern analysis to identify hominin involvement within a site. He proposed that the crack and twist method which was part of the osteodentokeratic industry hypothesis was the only way to produce spiral fractures, making spiral fractures diagnostic of hominin involvement (Dart, 1957). These claims were later rebutted through actualistic experiments and observations of carnivore bone modification (Haynes, 1983). Brain pointed out that carnivores were the main accumulators by matching perforations on a hominin skull to the teeth of a carnivore jaw (Brain, 1983). Actualistic experiments and observations also supported the claim that carnivores have the capability to produce spiral fractures (Johnson, 1985). Furthermore, Myers et al. (1980) pointed to spiral fractures within paleontological sites in North America long before the dispersal of hominins out of Africa. All

these pieces of evidence point to spiral fractures by themselves are a poor indicator of hominin involvement (Behrensmeyer, 1987).

To produce spiral fractures, dynamic and static loading need to operate on fresh bone (Johnson, 1985). Spiral fractures form when the structural integrity of green bone fails under stress, either by carnivore jaw or percussion, causing fragmentation as a way for the bone to release the energy (Capaldo & Blumenschine, 1994). The fracture follows collagen fibers that are spirally organized on the longitudinal axis of the bone shaft, leading to spiral fractures (Johnson, 1985). Green bone produces spiral fractures when loaded by dynamic or static processes. This association between fracture type and loading highlights the importance of bone freshness. When bone dries out microfractures form along the diaphysis encouraging fractures to occur through these weakened sections creating transverse fractures (Johnson, 1985). This biomechanical property of bone can be used to infer the overall condition of bone when it was fractured (Villa & Mahieu, 1991). The nutritive phase of a bone is when it is still fresh and hominins and carnivores can extract nutrients from it (Marean et al., 2000). The non-nutritive phase of a bone is when it is not appealing to carnivores or hominins anymore (Marean et al., 2000). Spiral fractures are associated with the nutritive phase of bone, while other fracture patterns like transverse and stepped are associated with the non-nutritive phase of the bone (Johnson, 1985).

Spiral fractures by themselves are not a good indicator of hominin behavior. Dynamic loading, however, can be associated with hominins (Johnson, 1985). Dynamic loading leaves a different pattern on bone, compared to static loading, due to the differential in energy release by the bone. Hackle marks and ribs are created as the energy from the hammerstone blow travels through the bone and dissipates (Capaldo & Blumenschine, 1994; Oliver, 1989). Hackle marks

can be described as imprints of radiating energy traveling through bone and leaving traces in the process as a means of stress relief (Fisher, 1995). Ribs are stress relief traces created when energy waves travel through the diaphysis in a straight line, leaving serrations in their wake (Johnson, 1985). A better way to visualize the difference between the two traces would be to imagine a water ripple as analogues hackle marks while a wave would best describe the traces left by ribs. Static loading does not exhibit this trace pattern; thus, hackle marks and ribs can be safely associated with dynamic loading (Johnson, 1985). .

The identification and analysis of bone surface modifications (BSMs) on faunal assemblages became commonplace as taphonomical considerations were integrated into paleoanthropological research (Gifford-Gonzalez, 2018d). They have been used in conjunction with skeletal part profiles and mortality profiles as auxiliary evidence. Because a growing body of scholarship indicated that skeletal part and mortality profiles did not reliably distinguish between actors, BSMs became the preferred method of analysis (Blumenshine, 1995). These marks can be subdivided into two general categories, BSMs linked to bone fragmentation and those created by the act of defleshing a bone (Fisher, 1995).

BSMs generated by bone defleshing are created by both hominins and carnivores (Blumenshine et al., 1996). Butchery BSMs are cutmarks, scrape marks and chop marks, while tooth marks and gnaw marks are BSMs associated with carnivores (Fisher, 1995). Both actors have analogous BSMs produced through a similar action, however tooth marks and cutmarks have been the most extensively studied and described (Shipman, 1981). Tooth marks are analogous to cutmarks since both are used to remove flesh from bone (Fisher, 1995). Cutmarks however tend to be parallel to the long axis of the bone, accompanied by microstriations, deep and V-shaped in cross section and usually have a “shoulder effect” where bone material is

displaced by the tool (Olsen & Shipman, 1988). Tooth marks are usually superficial, curved, V to U shaped in profile, and sometimes can have a shoulder (Shipman, 1981). While there is an overlap between mammalian toothmarks and cutmarks, with training the two can be distinguished with some certainty (Blumenschine et al., 1996; but see Njau & Blumenschine, 2006). Actualistic studies have provided evidence that tooth marks segregated to the epiphysis and occurring in about 20% of the assemblage is indicative of hominin action (Blumenschine, 1995).

The other category of BSMs is related to bone fragmentation. BSMs like peeling, flake creation, and heavy fragmentation are associated with bone fragmentation. The BSM that could be the most diagnostic in differentiating between carnivore and hominin involvement are bone flakes. Bone flakes share a similar creation process with lithic flakes (Vettese et al., 2020). Just like lithic flakes, bone flakes can be created when the loading on the bone is dynamic like a percussive blow dealt to the diaphysis of the bone (Fisher, 1995). Additionally, bone flakes can also be created through static loading as in pressure flaking, not dissimilar to lithic pressure flakes (Johnson, 1985). Percussion flakes can exhibit a platform and a bulb (Fisher, 1995), stress marks (hackle marks and ribs) (Fisher, 1995), greater breath than length (Vettese et al., 2020) and an absence or reduction in cortical bone (Vettese et al., 2020), however as indicated by Fisher (1995) some of the bone flake characteristics can be missing. However these traces are often erased by carnivores during bone fragmentation, leading to an overlap between hominin induced fragmentation, and an equifinality (Vettese et al., 2020).

Percussion notches and percussion marks have been shown to be diagnostic in distinguishing hominin created traces from carnivore generated traces (Blumenschine & Selvaggio, 1988; Capaldo & Blumenschine, 1994). Percussion notches are “semicircular to

arcuate indentations of the fracture edge of a long bone that are produced by a dynamic or static loading on cortical surfaces...leaving a negative flake scar that extends through the entire thickness of the bone and onto the medullary surface" (Capaldo & Blumenschine, 1994, p. 730). Percussion marks are described as pits and grooves present on the cortical bone surface, accompanied by microstriations present within the pits and grooves or emanating out of them (Blumenschine & Selvaggio, 1988). Percussion pits are rounded depressions present on the cortical surface of bone along the fracture edge (Blumenschine & Selvaggio, 1988). They are created by the natural protrusions present on the hammerstone and the anvil (Blumenschine & Selvaggio, 1988). Percussion grooves are like percussion pits but more oblong and are created by the hammerstone or anvil sliding and gouging along the bone surface as opposed to imprinting into the cortical surface (Blumenschine & Selvaggio, 1988). A good illustration would be to think of pits as depressions made by a stick in the sand, while grooves are lines created by skilling the tip of a stick along the sand. In addition to percussion pits and grooves percussions marks can also encompass striation patches. A key distinction between striation patches and pits and grooves is the size and depth of the striations (Vetese et al., 2020). Striations exhibit as long, parallel and superficial bone surface modification traces, while pits and grooves are smaller and deeper (Vetese et al., 2020), although striations often accompany pits and grooves (Blumenschine, 1995). Perhaps a good analogy might be to think of pits and grooves as points and broken lines drawn into the sand, while striations are more akin to a stick being dragged along the sand. Percussions pits and percussion notches appear at a frequency of about 38% in hominin modified assemblage (Blumenschine, 1995).

Capaldo & Blumenschine (1994) work on percussion and carnivore notches showed that notch dimension ratios and release angles were able to distinguish between carnivore and

hominin modified limb bones in size 1 and 2 animals, but not in size 3. Notch dimensions were defined as notch breath, notch depth and flake scar breadth. The ratios created attempted to quantitatively describe the notch shape and the flake dimensions. Notch breadth to notch depth describe the notch shape. Carnivores create more deeper notches while percussion creates more shallower notches. Flake scar breadth to notch depth describe the dimensions of the missing flake. Thicker flakes are created by carnivores and thinner flakes are produced by percussion. This actualistic research provides the means to differentiate between carnivore and hominin modified bones with some limitations. While notches might be irrelevant past size 3 animal bones, percussion marks are still diagnostic of hominin feeding behavior due to the presence of microstriations (Blumenshine & Selvaggio, 1988; Fisher, 1995).

Other actors besides hominins and carnivores have been investigated in open air site settings. Herbivores and rodents have been known to modify bone (Gifford-Gonzalez, 2018c). Herbivores usually engage with bones due to a calcium deficiency, however their taphonomic signature is minimal at best (Gifford-Gonzalez, 2018b). Rodents like porcupine accumulate bones and use them to file down their incisors (Fisher, 1995). Porcupines prefer dry bone so their tooth marks are usually on dry or permineralized bone which is easily identified (Gifford-Gonzalez, 2018b). Trampling is another biotic modification to bone without intent, which involves stepping on and kicking bones that are present on the ground (Olsen & Shipman, 1988). Trampled bones can be broken if weathered enough, and the act of trampling can cause cutmark like trample marks by scraping the bone on sand particles (L. A. Borrero, 1990; Olsen & Shipman, 1988). These pseudo-cutmarks have random orientations, random lengths, and do not correspond to any muscle attachment sites on the bone (Olsen & Shipman, 1988). Trampled fragments also tend to be pushed perpendicularly into the ground (Blasco et al., 2008).

Actualistic studies have attributed notches on the cortical edge of bone fragments to trampling (Blasco et al., 2008).

Abiotic processes have also been investigated as actors of bone fragmentation.

Weathering is the exposure of bones to the environment (Behrensmeyer, 1978). This causes bones to dry out and overtime lose integrity through exfoliation (Karr & Outram, 2015).

Weathering can eventually cause bone fracture like the fracture patterns seen in dry bone (Fisher, 1995). Finally, sediment pressure has been known to fracture bone (Villa & Mahieu, 1991). Due to the predictable nature of sedimentation seen in open air sites, sediment pressure builds up slowly on the bone, allowing diagenetic processes to act on the microscopic structure of bone, replacing or leaching out calcium and weakening the overall structure of the bone (Grupe & Harbeck, 2014). By the time that the sediment pressure is enough to break the bone, the fracture pattern is consistent with dry bone (Villa & Mahieu, 1991).

Many actors contribute to the BSM observable in faunal assemblages from open air sites. Carnivore and hominin are identified most frequently as the actors responsible for much of the taphonomic processes that impact the paleoanthropological record. However other less studied actors do contribute to the formation of open air assemblages. To get a holistic view of bone accumulations all actors need to be investigated and accounted for, before the taphonomic pattern associated with hominins can be fully understood.

### **2.3 Traces and Cave Site Taphonomy**

Caves have been of archaeological interest because of their use by hominins for shelter and storage. Caves offer protection from the elements and the vagaries of seasonal temperature change. For those reasons, caves often preserve the archaeological record better than open air sites (Gargett, 1999). However, caves also present interesting challenges to taphonomic analyses.

Caves are uniquely created by forces that hollow out a cavity in the bedrock thus giving each cave a unique environment (Gargett et al., 1989). This uniqueness extends to the types of possible actors that can interact with a bone assemblage such as cave roof fall, the rate of deposition and the overall humidity of the cave. Deposition can also be fast and unpredictable. Roof fall events quickly add a depositional layer, modifying any bones present on the cave floor, or bones that are partially buried (Gargett, 1999). Underground streams can completely erase the depositional history of the cave by eroding away the cave floor and leave a sink hole (Gargett et al., 1989). All these forces need to be taken into consideration when applying methodologies developed for open air site taphonomy to cave taphonomy.

Animals have used caves for a multitude of reasons. Carnivores made use of caves as burrows and food cache locations promoting the accumulation of bones within caves as accumulators and eventually as part of the assemblage upon their death in the cave (de Ruiter & Berger, 2000; Kurtén, 1995). Hominins have used caves for shelter and homes especially in the Middle and Late Pleistocene acting as accumulators of animal bones, and upon their death becoming part of the assemblage (J. Richter, 2006; Sala et al., 2016). However, carnivores and Pleistocene hominins are not the only groups that use caves. Herbivores have been known to use caves for shelter or as sources of water and food (Gargett et al., 1989). Chimpanzees use of caves as shelter or for food has been recorded (Boyer Ontl & Pruetz, 2020). This chimpanzee behavior hints at Pliocene hominins engaging in cave use prior to hominin dispersal out of Africa. Cave use by animals implies that at times they died in caves as well making caves productive sites of bone accumulation.

As a unique environment, caves require innovative methodologies to explore the taphonomic history of a bone assemblage. Much of the methodologies and theory created for

testing the taphonomic history of open air sites can be applied to caves. The nestled hierarchy seen in Figure 2 can still be used to link a trace to a causal agent and so on until an actor is identified (Gifford-Gonzalez, 1991). Similarly traces left by hominins and carnivores in caves are the same as the traces left on bone within an open air site. In this regard a cutmark in a savannah setting is the same as a cutmark in a cave setting (Binford, 1981b). Open air sites and caves do share some depositional and erosional forces like wind, water, and mass earth movements (Gargett, 1999; Gargett et al., 1989) Differences between the two settings arise from the unique environments seen in caves and the depositional forces unique to caves such as cave roof fall.

**Table 1** Archaeological and Paleontological Cave Sites with Evidence of Cave Roof Fall

| Site           | Country        | Site Type       | Time period (kya) | Roof fall fragment size (m) or description | Weight in kg (if provided ) | Reference   |

| <i>The average bedrock fragment size was between 7 cm and &gt;770 cm. The minimum average rock fragment size was calculated by picking the smallest reported value, or quantifiable size description (e.g 0.4 cm for a pebble). Boulder values were set at 25.7 cm in diameter. The maximum average rock fragment size was calculated by picking the largest reported value, or quantifiable size description. Boulders were not included in the average because they do not have a maximum value. To compensate for this a greater than sign was placed in front of the maximum average value to indicate that the actual maximum size of a rock fragment is larger than reported here.</i> |              |                |        |                              |    |  |

In the past much of the research done on bone fragmentation actors have been relegated to hominins and carnivores, since both are intentional actors seeking the nutritive qualities of fresh bone (Johnson, 1985). While this focus has provided criteria to distinguish the two, other actors of bone fragmentation have not been as extensively researched. Roof fall is one of these actors, with a paucity of research done on roof fall even though its presence is seen at many cave sites (L. Borrero et al., 2007; Goldberg et al., 2018; Solecki, 1957). Roof fall is the weathering of bedrock until a piece decouples from the bedrock and is pulled by gravity towards the cave floor (Gargett, 1999). The weathering of the bedrock can be due to water, or due to temperature fluctuations (Mann & Monge, 2006). The size of the chunk of rock depends largely on the bedrock composition and on the intensity of weathering but can range from pebbles to pieces the size of cars or larger (Gargett et al., 1989). Large roof fall events are maintained in the stratigraphic record of the cave as slabs and serve as clear indicators of a roof fall event. These

can be seen in cave sites like Pech IV (France, 99-45 kya), Shanidar (Iraq, 70-60 kya), Misliya (Israel, 260-170 kya) (Goldberg et al., 2018; Mina et al., 2010; Trinkaus, 1983). However smaller pieces of bedrock can detach, interact with bone assemblages, and disappear from the record through fragmentation, weathering, or displacement as seen in Table 1 (Mann & Monge, 2006; Oliver, 1989). The interaction between smaller pieces of bedrock and bone assemblages could create spiral fractures and masquerade as a hominin created spiral fracture (Dixon, 1984; Griggo et al., 2019; Oliver, 1989).

Spiral fractures paired with stress relief traces (hackle marks and ribs) are informative of the moisture content of bone (Johnson, 1985). These traces are associated with the fracture of fresh green bone due to its ductile properties (Karr & Outram, 2012b). Fragmentation of dried bone produces transverse and stepped fractures due to the loss of ductile properties associated with green bone (Johnson, 1985). In open air sites bones are exposed to the full brunt of the elements, which cause bones to lose moisture, drying out the bone in the process at an accelerated rate (Behrensmeyer, 1978). Caves can mitigate moisture loss due to their enclosed nature extending the green state of bone past what has been recorded in an open air site (Gargett, 1999). Since cave environments promote the retention of moisture within bone, extending its green qualities it is possible for roof fall to interact with bone and create spiral fractures similar to those created by hominins causing an equifinality (Dixon, 1984; Gifford-Gonzalez, 1991; Johnson, 1985; Oliver, 1989).

**Table 2** Traces of Dynamic Loading on Bones Modified By Hominins at Open Air Sites and Roof Fall at Cave Sites

| Dynamic Loading at Hominin Open Air Sites                    | Dynamic Loading at Cave Sites with Roof Fall                |
|--|---|
| Percussion notches (Blumenschine, 1988)                      | Percussion Notches (Oliver, 1989)                           |
| Percussion marks (Blumenschine, 1995)                        | Percussion marks (Oliver, 1989)                             |
| Bone flakes (Blumenschine, 1988)                             | Bone flakes (Oliver, 1989)                                  |
| Stress relief traces (hackle marks and ribs) (Johnson, 1985) | Stress relief traces (hackle marks and ribs) (Oliver, 1989) |

Research into roof fall as an actor is minimal when compared to the research in hominin or carnivore bone modification patterns, however the research done has provided some definition to roof fall. Oliver (1989) points out that roof fall does operate through dynamic loading by investigating the assemblage created within the Shield Trap cave (USA, between 9.2 to .62 kya). The Shield Trap cave assemblage was created independent of hominin intervention, and credits roof fall with the fragmentation observed (Oliver, 1989). Traces linked to dynamic impact are seen in the assemblage manifesting as stress relief traces (hackle marks and ribs) (Johnson, 1985; Oliver, 1989). Additionally, percussion notches and percussion marks are identified, providing evidence that roof fall can mimic hominin percussion as seen in Table 2 (Griggo et al., 2019; Oliver, 1989). Mann and Monge (2006) present evidence of a sliver of roof fall interacted with the skull of a Neanderthal in Krapina. After they rule out all interpersonal conflict and other types of traumas on the morphology of the trauma seen on the parietal bone, they concluded that roof fall is the likely culprit (Mann & Monge, 2006). Mann and Monge (2006) provide further evidence that a small sliver of roof fall can detach from the bedrock, alter bone, and then disappear from the record. Dixon (1984) presents evidence that carnivores and roof fall can interact on the same assemblage. He points out that at Porcupine River Caves (USA, between 21 to 3.4 kya) roof fall is evident in blocks preserved on the cave floor and as pseudo-cultural traces left on bone, hinting at interactions between bone and bedrock particles, followed by carnivore ravaging

(Dixon, 1984). This interaction could mimic human and carnivore modification of bones, where roof fall fractures the diaphysis exposing bone marrow, followed by carnivores extracting the bone marrow and deleting the epiphysis, leaving behind a pattern observed by Blumenschine (1995) in the hammerstone to carnivore assemblage. This scenario is further supported by actualistic research done by Karr and Outram (2012). After subjecting bones to multiple episodes of simulated roof fall events they found that roof fall has an inverse relationship to density mediated attrition seen within carnivore assemblages (Karr & Outram, 2012a). Due to the spongy nature of epiphyseal ends allows the articular ends to remain intact following contact with roof fall events, whereas the diaphysis gets deleted due to its rigid nature (Karr & Outram, 2012a). All these examples show that roof fall has the potential to modify bones in a similar manner to hominin percussion and disappear from the record, thus producing a pseudo-archaeological site, which can be interpreted as human modified with or without the input of carnivore actors.

The lack of data and research on roof fall is the focus of this thesis. One goal of the experiment that is at the core of this thesis is to create a roof fall reference collection through an actualistic experiment. Even though the roof fall reference collection is small ( $n=16$ ), it is a first step towards understanding the taphonomic pattern of roof fall. The other goal is to compare the pattern left by roof fall to the pattern generated by hammerstone-on-anvil percussion. This is crucial because as Oliver (1989) indicates that both actors leave similar traces, operate through the same causal agent and effector which leads to a possible equifinality (Gifford-Gonzalez, 1991). The roof fall reference collection will be used to attempt to solve this equifinality with the goal being to provide the necessary criteria to recognize roof fall as an actor and separate it from hominin generated assemblages.

## CHAPTER III: MATERIALS AND METHODS

### 3.1 Materials

For a comprehensive list of materials, see Table 18 in the Appendix.

### 3.2 Methodology

#### *Setup for cave roof fall actualistic study*

Sixteen (n=16) bison bones were broken during the cave roof fall actualistic study. The age of the slaughtered bison is approximated to older than four and a half years but younger than five and a half years. This estimate was based on the complete fusion of the distal tibial epiphysis and the lack of fusion of the proximal tibial epiphysis (Koch, 1935). The sex of the slaughtered bison was unknown. Both left and right tibiae were used without any preference. According to Meagher (1986), the age bracket of four and a half and five and a half would categorize all animals as mature regardless of sex. Mature bison weigh between 318 kg to 907 kg (Meagher, 1986), placing the slaughtered bison in a size 4 category (Blumenschine, 1986; Diez et al., 1999). The tibiae assigned to the cave roof fall actualistic study were received frozen due to weather delays caused by a blizzard and other snowy conditions. The bones were thawed when they were broken.

Bone condition (e.g., frozen, refrigerated, or thawed) was considered because of its effect on bone freshness and fracture mechanics (Grunwald. 2016, Outram and Karr, 2015). Outram and Karr (2015) remark that refrigerated bones maintain their freshness longer than thawed bones. To maintain refrigeration temperature ice and salt were used respectively to keep the tibiae cool during warm temperatures and prevent the tibiae from freezing during colder temperatures. Freezing was discouraged to prevent the freeze thaw cycle from further alerting the microstructure of the diaphysis (Grunwald, 2016).

Bone freshness was a condition that was controlled for. Fracture patterns produced by dry bone can be distinguished from fracture patterns on fresh bone (Johnson, 1985). This means that a cave roof fall event on dry bone can be distinguished from fresh bones percussed by hominins through the resulting fracture patterns (Karr & Outram, 2012b). However, if a cave roof fall occurs on a living animal or fresh bones, the fracture patterns produced by this event would be comparable to hammerstone-on-anvil percussion. This is because both actors are believed to leave the same traces, utilize the same causal agent and use the same effectors (Gifford-Gonzalez, 1991; Oliver, 1989). To investigate this the bones were broken fresh and thawed to mimic bone condition that would be desirable to a hominin.

**Table 3:** Measurements of boulders used in the cave roof fall simulation

| Assigned number  | Type      | Weight (kg) | Length (cm) | Width (cm) | Diameter (cm) |
|--|-----------|-------------|-------------|------------|---------------|
| 1  | Sandstone | 6.8         | 22.9        | 12.7       | 26.2          |
| 2  | Sandstone | 13.6        | 33          | 15.2       | 36.3          |
| 3  | Sandstone | 6.8         | 22.9        | 20.3       | 30.6          |
| 4  | Sandstone | 13.6        | 33          | 22.9       | 40.2          |
| <u>Rock fragment categories and associated sizes.</u>                                |           |             |             |            |               |
| Granule- rock fragment with a diameter between .2 and .4 cm (Hill, 2003)             |           |             |             |            |               |
| Pebble- rock fragment with a diameter between .4 and 6.4 cm (Hill, 2003)             |           |             |             |            |               |
| Cobble- rock fragment with a diameter between 6.4 and 25.6 cm (Hill, 2003)           |           |             |             |            |               |
| Boulder- rock fragment with a diameter larger than 25.6 cm (Hill, 2003)              |           |             |             |            |               |
| Gravel- loose of unconsolidated deposit of pebbles, cobbles or boulders (Hill, 2003) |           |             |             |            |               |

*Figure 3 Boulder number 1 (6.8 kg)*

*Figure 4 Boulder number 2 (13.6 kg)*

*Figure 5 Boulder number 3 (6.8 kg)*

Four sandstone boulders were procured for the cave roof fall actualistic study. The boulders weights and dimensions were settled upon after conducting a survey of the literature as seen in Table 1. The average range of cave roof fall fragments falls between 7 and >770 cm. Boulder sized bedrock particles have been described at most cave sites with reported cave roof fall. The selected rocks fall within this average and have a diameter that can be described as boulder as seen in Table 3. A more conservative diameter (e.g., closer to 25.7 cm) was picked to test if a more conservative sized rock can damage bones. The only reported weight of roof fall blocks was between 400 and 500 kg as seen in Table 1, which would have not been feasible for this experiment (Dixon, 1984). A more feasible weight of 6.8 kg and 13.6 kg boulders was settled upon. These weights were selected because this experiment relies on an individual powered pulley system to hoist up a boulder up using a pulley system. The weights suggested by the literature are not attainable without machinery. Two boulders of each weight were procured as a contingency if one of the boulders broke or became damaged beyond use. The dimensions of the impact face and weight of all four boulders are summarized in Table 3. The boulders that were used in the experiments can be seen in Figure 1-3.

**Table 4:** Pleistocene Archaeological Rock Shelter Sites with Cave Heights

| Cave                   | Country        | Time Period (kya) | Height (m)    | Source   |
|------------------------|----------------|-------------------|---------------|--|
| Pod Hradem             | Czech Republic | 57-29             | 1.5-7         | (Lisiecki & Raymo, 2005; Nejman et al., 2018)                |
| Kobeh                  | Iran           | 250-35            | more than 3.2 | (Marean & Kim, 1998)   |
| Bisitun                | Iran           | 243-57            | 4             | (Lisiecki & Raymo, 2005; Trinkaus & Biglari, 2006)           |
| Jarama VI              | Spain          | ~50               | 4             | (Kehl et al., 2013)  |
| Veternica              | Croatia        | 96-82             | 4             | (Karavanić et al., 2017; Lisiecki & Raymo, 2005)             |
| Zhoukoudian Upper Cave | China          | 38.3-33.5         | 4-8           | (Li et al., 2018; Norton & Gao, 2008)                        |
| Spy                    | Belgium        | 36                | More than 4.5 | (Fernández-Jalvo & Andrews, 2019; Toussaint & Pirson, 2006)) |
| Cro-Magnon             | France         | 30                | 5             | (Henry-Gambier et al., 2013)                                 |
| Scladina               | Belgium        | 80                | 6             | (Pirson et al., 2018)  |
| Moula-Guercy           | France         | 191-71            | 8             | (Lisiecki & Raymo, 2005; Valensi et al., 2012)               |
| Velika Pecina          | Croatia        | 191- 14           | 8             | (Karavanić & Smith, 1998; Lisiecki & Raymo, 2005)            |
| Vindija                | Croatia        | 114-28            | 10            | (Wolpoff et al., 1981)                                       |
| La Naulette            | Belgium        | Pleistocene       | 11            | (Toussaint & Pirson, 2006)                                   |
| Krapina                | Croatia        | 130               | 12            | (Trinkaus, 1985)   |
| Shanidar               | Iraq           | 70-60             | 13.7          | (Reynolds et al., 2018; Solecki, 1957)                       |
| Gran Dolina            | Spain          | 730-244           | 18            | (Blasco et al., 2010)  |

The average of all cave heights is between 7.3 m and >12.3 m. The minimum was calculated by averaging the minimal cave heights provided, while the maximum was calculated by averaging the maximum cave height provided. Cave heights that did not have a reported maximum (e.g Marean & Kim, 1998) were not included in the maximum average. To compensate for this a greater than sign was used to indicate that the actual maximum cave height might be larger than the one calculated.

The heights, from which the sandstone boulders were dropped, were selected by surveying the literature for Pleistocene cave sites in Europe, the Levant region and Asia (see

Table 4) and then simplifying them to make it feasible to conduct the experiment. Some measurements are from the entrance or mouth of the cave, while others are from the internal chamber of the cave. This was also done because some of the literature only provided cave heights at the mouth of the cave or did not specify if the measurements were from the mouth or the internal chamber. Where the cave height measurements are from is not important, because a cave roof fall event can happen anywhere in the cave, from the entrance to the inner chamber. This is because bones can be transported to the cave's mouth or to the inner chamber of the cave by carnivore, hominin, or abiotic actors (Gifford-Gonzalez, 1991; R. L. Lyman, 1994; Marra et al., 2004; Oliver, 1989). This means that a falling bedrock fragment has just as much of a chance to impact a bone at the mouth of a cave as it does in the inner chamber. The heights presented in Table 4 range from 1.5 m to 18 m with an average cave height between 7.3 m and >12.3 m. While heights from 1.5 m to about 3 m can be achieved using a ladder, heights above 3 m becomes progressively harder to accomplish without heavy machinery or an accessible structure, such as a tree or a building. Due to the novelty of this experiment and the lack of drop height standardization, drop height increments needed to be generated. The drop height maximum of 7.6 m was selected because it was an achievable height by using tree branches. Additionally, the drop height of 7.6 m surpasses, or is close to most cave heights listed in Table 4 and is within the average range. This allows the maximum drop height of 7.6 m to become an analog for the height of an average cave. The drop height of 4.6 m was selected because it is within a 3 m increment of the maximum drop height of 7.6 m. This height is representative of the lower range cave height. A height of 4.6 m was also picked to investigate if a more conservative cave height could modify bones. The larger drop height is representative of an average cave, while the smaller drop height could be representative of smaller caves.

The necessary boulder drop heights were identified using rope and markers. For the drop heights of 4.6 m and 7.6 m, a tree branch pulley system was employed to reach the desired drop heights. The boulder drop heights were verified by marking a rope at 9.2 m and 15.2 m, looping the rope around a promising branch, and then aligning the beginning of the rope or zero, with either 9.2 m, for 4.6 m or 15.2 m for 7.6 m on the ground. If the two markers aligned, then the branch was selected.

*Figure 6 Tibia positioned on tarp underneath the boulder*

A tarp was placed on the grass underneath the hoisted block of sandstone. In preparation for the drop, a tibia was placed on top of the tarp as seen in Figure 6. The purpose of the tarp was to enable the easy identification and recovery of bone fragments and prevent any bone fragments from getting lost in the grass.

#### *Cave roof fall actualistic study*

The 16 tibiae used in the cave roof fall actualistic study were equally divided into four experiments. Each experiment was assigned a height value of either 4.6 m or 7.6 m. This would be the height from which the boulder would be dropped on a tibia. These heights, 4.6 m and 7.6 m are an artificial stand-in for cave height. Each experiment was also assigned a boulder that

weighed either 6.8 kg or 13.6 kg. This would be a stand-in for a bed rock fragment coming loose from the cave wall. The purpose of multiple drop heights and boulder weights was to investigate if drop height and boulder weight have any influence on bone modification. Each boulder would simulate a bedrock fragment coming loose from the cave roof and impacting a bone located on the cave floor.

*Figure 7 Rock fastened with string*

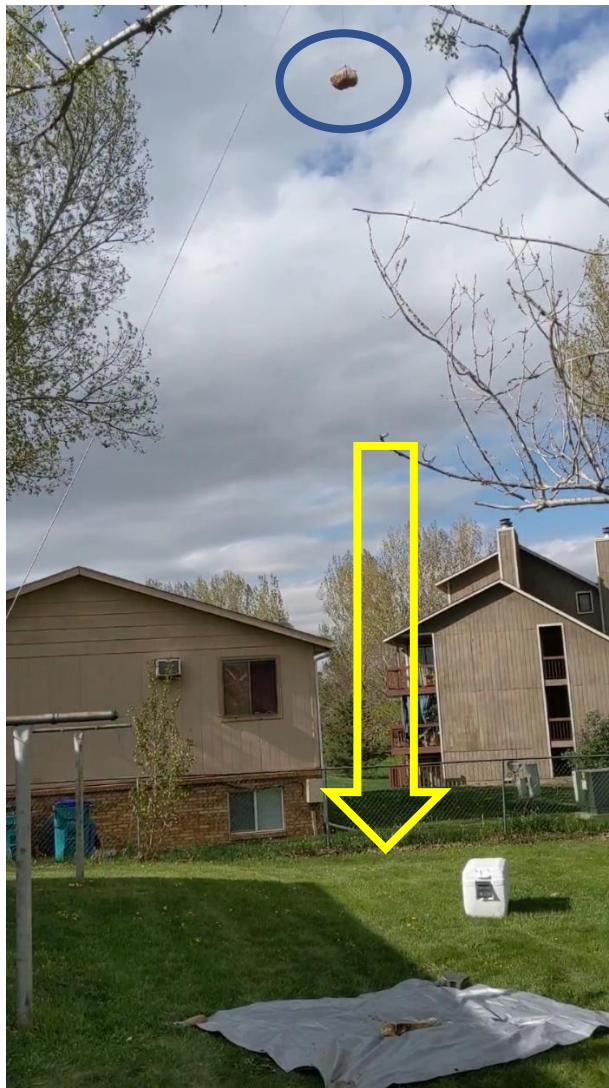

Figure 8 Cave roof fall simulation

To simulate a cave roof fall event the following protocol was developed. A tarp was placed on grass to prevent any bone fragments from getting lost (Figure 6). The tibiae were placed on the tarp one at a time with the medial side facing upwards. There was one exception which is discussed below. At this point the tibiae were thawed and did not freeze again. The boulder was secured with rope, positioned above the middle of the diaphysis of each tibia and then lifted to the desired drop height by pulley action as seen in Figure 7. Care was taken to not allow the rock to contact the tibia before the drop to prevent the creation of any bone surface modifications on the bone. Because the desired drop height was the height of a branch, the

boulder was at the appropriate drop height when it was adjacent to tree branch. After a countdown the boulder was released to fall on the bone. If the boulder contacted the bone, the tibia was inspected for breakage. If the diaphysis of the bone was split open, this was considered breakage. If the diaphysis was not clearly broken, the bone was twisted. This action was done because the periosteum was not removed from the bone, which can hold a bone together even if the diaphysis is broken (Pickering & Egeland, 2006). The bone twisting was done by grabbing the epiphysis and applying torsional force to the bone. If the tibia was easily twisted apart, the bone was considered broken. Once the bone was considered broken it was placed in a plastic bag. A number from one to sixteen, starting with the first bone, was assigned to each bag. If the tibia did not look broken, or was not easily twisted apart, the bone was placed back on the ground. The boulder was then reset for another drop. Each drop represents a cave roof fall event and was considered one trial. This reset was done to account for the possibility that a previously impacted bone could be subjected to another cave roof fall event. This design does not account for bones that are not broken by a roof fall event prior to their burial, however as presented by Oliver (1989) and Dixon (1984) roof fall events do fracture impacted bones. This could be a blind spot for this experiment, however breakage was part of the experimental design, to create a cave roof fall assemblage as close to a hominin created assemblage as possible. A drop was considered a trial regardless of whether the boulder contacted the bone. If the bone failed to break after the tenth trial the experiment ended. The ten trials cut off point was arbitrary but grounded in reason. The number of necessary roof fall events to cover and protect a bone from further roof fall damage is unknown. This is because variables like the diameter of the bedrock fragment, the friability of the parent material, the contact angle of impact among other factors are either unknown or unpredictable. With that amount of unpredictability, it was assumed that ten

cave roof fall events would be enough to cover and shield the bone from further roof fall damage.

**Table 5** Cave Roof Fall Simulation Summary with Defined Drop Height and Boulder Weight For Each Experiment

| Bone Number | Bone Side | Experiment Number | Drop Height (m) | Boulder number | Boulder Weight (kg) | Bone ID   |
|-------------|-----------|-------------------|-----------------|----------------|---------------------|-----------|
| 1           | Left      | 1                 | 7.6             | 2              | 13.6                | ASH-T-001 |
| 2           | Right     | 1                 | 7.6             | 2              | 13.6                | ASH-T-002 |
| 3           | Right     | 1                 | 7.6             | 2              | 13.6                | ASH-T-003 |
| 4           | Left      | 1                 | 7.6             | 2              | 13.6                | ASH-T-004 |
| 5           | Left      | 2                 | 7.6             | 1*3            | 6.8                 | ASH-T-005 |
| 6           | Right     | 2                 | 7.6             | 3              | 6.8                 | ASH-T-006 |
| 7           | Left      | 2                 | 7.6             | 3              | 6.8                 | ASH-T-007 |
| 8           | Right     | 2                 | 7.6             | 3              | 6.8                 | ASH-T-008 |
| 9           | Right     | 3                 | 4.6             | 3              | 6.8                 | ASH-T-009 |
| 10          | Left      | 3                 | 4.6             | 3              | 6.8                 | ASH-T-010 |
| 11          | Right     | 3                 | 4.6             | 3              | 6.8                 | ASH-T-011 |
| 12          | Right     | 3                 | 4.6             | 3              | 6.8                 | ASH-T-012 |
| 13          | Right     | 4                 | 4.6             | 2              | 13.6                | ASH-T-013 |
| 14          | Left      | 4                 | 4.6             | 2              | 13.6                | ASH-T-014 |
| 15          | Left      | 4                 | 4.6             | 2              | 13.6                | ASH-T-015 |
| 16          | Right     | 4                 | 4.6             | 2              | 13.6                | ASH-T-016 |

\*Rock(riprap) #1 only used for one drop because it broke upon impact. Rock #3 used for remainder of experiment  
Lateral side of bone number 5 used due to the presence of cut marks from butchering on the medial side

The cave roof fall actualistic experiment was broken down into four experiments. Each experiment paired a drop height with a boulder weight to simulate a cave roof fall event as seen in Table 5. Four tibiae were assigned to each experiment. Each tibia was subjected to the cave roof fall simulation individually as described above. The tibia placed on the tarp with the medial side facing up. The only exception was bone 5 which was placed with the lateral side facing up due to butcher marks present on the medial side. This was done to prevent the butcher marks from confounding the expression of bone surface modifications that were collected later.

After all experiments were carried out a pattern became apparent. All four experiments produced bone fragmentation. Once all the experiments were completed the bagged bones were stored in a cooler without ice to await processing. Ice was not used to chill the bones because the condition of the bones was no longer of importance, though care was taken to make sure that the temperature of the bones did not get too extreme. Bone condition became irrelevant because fracture patterns and BSMs which are dependent on bone condition, are present and imprinted on the bone and cannot be erased if the bone loses moisture or becomes frozen.

*Figure 9 Bone in canning pot*

## *Bone Processing*

The next step was fully defleshing and degreasing the bone fragments through simmering. All fragments from a bag were placed together in one of two large enamel canning pots as seen in Figure 9. Care was taken to boil the contents of one bag in one pot at a time. Water was added until the fragments were submerged, with an additional 2.5 cm of water added on top. One cup or 0.25L of 20 Mule Team borax and 0.25L of odorless and clear Ecos Plus Liquid Laundry Detergent with enzymes was added to each pot. Ecos Plus Liquid Laundry Detergent was selected because this plant-based detergent with enzymes does not damage the bone during simmering. Additionally, the enzymes help breakdown grease more efficiently. Borax was used to boost the cleaning and degreasing power of the plant-based detergent. Like the detergent borax does not damage the bones. The water was heated on high with the canning pot covered until boiling and then left to simmer for approximately eight hours on medium heat with the canning pot partly covered. The number that was assigned to each bone bag was written on a piece of paper, which stayed with the pot throughout the process. Simmering the bones guaranteed that any remaining flesh was removed, and fat in the bone, including the bone marrow was extracted. After the bone fragments were boiled for a minimum of eight hours, large bone fragments were removed, rinsed and the pots were emptied in a sink with a 1 cm mesh over the drain. Any fragment that was caught in the mesh was collected, cleaned, and placed with their respective bone number. The number written down at the beginning of the simmering process accompanied the bone fragments throughout the cleaning process. The tibial fragments were left to dry indoors overnight. The following day the bone fragments were placed in a paper bag, with their respective number stabled to the bag, and left to dry outside in a plastic bin for two days. The plastic bin had small holes drilled into it that allowed airflow and dissipated any

humidity. The holes were small enough to prevent any animals from attacking or modifying the bone fragments. After the bones were left to dry outside for two days the bags were brought indoors and left to dry further for an additional two days.

Once all the tibial fragments were boiled and left to dry outside in a perforated plastic bin for two days and indoors for at least two days, the bone fragments were given a 12% hydrogen peroxide bath. This step ensured that the bones were sterilized and ensured against any future mold assaults. This step was taken so the bones could be safely stored within the 3D imaging and analysis laboratory at Colorado State University. After the bones were soaked in the 12% hydrogen peroxide solution, they were left to fully dry indoors for at least two days. Once the bones fully dried, they were accessioned.

During the experiment the bones were numbered from one to sixteen. After the bones were fully processed, they were given an accession number (Bone ID). The accession number started with “ASH-T-” followed by one to sixteen as seen in Table 5, which corresponded to the number that was initially given to each bone during the simulation. The same accession number was placed on large bone fragments, and any fragments that could accommodate an accession number without covering any vital marks. Smaller bone fragments were placed together in a small plastic bag with the appropriate accession number written on it. To ensure that the accession number will not be removed by other means, a coat of clear nail polish was applied to each fragment, in a discreet place, after which the proper accession number was written on the nail polish strip using a fine point sharpie. A second layer was applied on top of the accession number to seal it. Once all the bone fragments were accessioned, they were transferred to a plastic bag, with the proper accession number written on it.

### *Percussion Sample*

Sixteen bison tibiae (n=16) broken by hammerstone, and anvil percussion were randomly selected from a collection of percussed tibiae and femurs currently residing at the 3D imaging and analysis laboratory at Colorado State University. This set of bones fragments are representative of the hominin percussion sample. Only tibiae were selected from the collection in order to eliminate bone density as a possible confounding variable in bone surface modification expression (Lam et al., 1998). A sample size of sixteen percussed tibiae was picked to match the number of tibiae broken by cave roof fall and to reduce any confounding variables that could promote the over-expression of bone surface modifications in the percussion sample. The bones were broken by students as part of a previous experiment. The hammerstone and anvil used in these experiments was a metamorphic rock. The hammerstone could be described as cobble size. These bones were processed in the same manner as the cave roof fall bones. The tibiae are catalogued under Robert Kaplan with accession numbers beginning in RSK. The similarity in processing manner is crucial because it means that there is the same quality of bone surface to observe bone surface modifications.

### **3.3 Data Collection from Fractured Bones**

Variables were collected from all bone fragments generated by the cave roof fall actualistic experiment and on the sample selected from the percussed bone collection. As seen in Table 6 collected variables were broken down into three major categories: visual, measured, and composite.

**Table 6:** Variables Collected from Fractured Bison Bones

| Collection Method  | Visual       | No Magnification             | Variables Collected   |
|--|--------------|------------------------------|---|
|  |              |                              | Fragment count<br>Flake count<br>Incipient notches<br>Notches<br>Fragments with cortical surface<br>Fragment with a notch<br>Fragments with a pit and/or groove<br>Pseudo-notches   |
|  |              | Magnification<br>3x and 10 x | Pits<br>Grooves<br>Striations   |
|  | Measurements | Presence/Absence             | Ribs<br>Hackle marks  |
|  |              | Linear Measurements (cm)     | Fragment size (in 1 cm categories) <sup>1</sup><br>Epiphyseal element length <sup>1</sup><br>Notch breadth <sup>2</sup><br>Notch depth <sup>2</sup><br>Flake scar breadth <sup>2</sup>                                      |
|  | Composite    |                              | Release Angle<br>Percentage of cortical fragments with pits and/or grooves<br>Percentage of cortical fragments with notches<br>Pseudo-notch to notch<br>Notch breadth to notch depth<br>Flake scar breadth to notch breadth |
| <p><sup>1</sup>Fragments were measured longitudinally. Epiphyseal elements were measured longitudinally from the metaphysis to farthest fracture edge.</p> <p><sup>2</sup>Measurements obtained using reusable molding material. Used only for ratios.</p> |              |                              |   |

Visual variables are further broken down into variables that required no magnification, variables that required magnification and present/absent features as seen in Table 6. Variables that required no magnification to collect such a fragment count, flake count, and fragments with a cortical surface were collected without any visual aid. Magnification of 3x (magnifying glass) and 10x (hand lens) were used to collect variables that required magnification to identify, which were pits, grooves, and striations. The last subcategory of visual variables was presence/absence

variables, which marked the presence or absence of stress relief traces (hackle marks and ribs) in both assemblages.

Measured variables were gathered using the aid of a digital caliper, tape measure or goniometer as seen in Table 6. A digital caliper was used for linear measurements of fragment length, epiphysial element length, notch breadth and depth, and flake scar breadth, however if the length of the fragment exceeded the caliper a tape measure was employed. A goniometer was used to measure the notch release angle.

Composite variables consist of ratios build from count or measured variables. Ratios as seen in Table 6 were used to investigate the relationships between two variables. This was done to “flatten” two variables into one and expose if the relationship between them is significant.

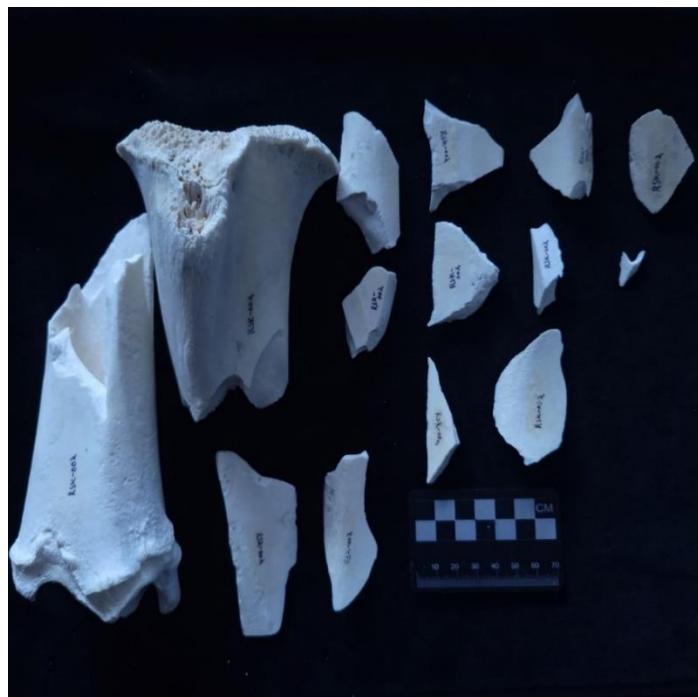

The experimental categories created during the cave roof fall actualistic study were maintained throughout data collection. Collected data within one experiment was not combined with other experiments. This precaution was taken to preserve any variations generated by a difference in boulder drop height or boulder size.

#### *Cave Roof Fall and Hammerstone-on-Anvil Variable Labeling*

A different way of labeling each of the assemblages was used to easily and clearly identify between bone surface modifications recorded in the cave roof fall assemblage from those in the hammerstone-on-anvil assemblage. Variables recorded from the cave roof fall experiment have the descriptor of “impact” attached to them (e.g., impact grooves, impact pits, impact notches). Variables gathered from the hammerstone-on-anvil percussion sample were given the descriptor of “percussion” (e.g., percussion grooves, percussion pits and percussion notches). This labeling convention is purely semantic to clearly identify traces created by one actor from the other. Identification wise the same criteria was used to for each collected BSM variable with

Blumenschine & Selvaggio (1988) used for percussion marks, White (1992) and Pickering & Egeland (2006) were employed to identify pits and striations, Capaldo & Blumenschine (1994) was applied to define notches, incipient notches, and pseudo notches, Vettese et al. (2020) was utilized for grooves, and bone flakes were identified using Fisher (1995) and Vettese et al. (2020).

### ***3.3.1 Visual-No Magnification***

*Figure 10 Hammerstone-on-anvil fragments*

*Figure 11 Cave roof fall created fragments*

#### *Fragment Count*

A bone fragmentation count was carried out on both samples. Each bag was emptied out on a foam surface along with any other smaller bags that were inside the larger bag. All fragments including the epiphyseal elements were counted. Cave roof fall experiments were counted separately from each other. Figure 10 shows an example of a fragmented assemblage created actualistically by hammerstone-on-anvil percussion. Figure 11 shows an example of a fragmented assemblage from the actualistic cave roof fall experiment.

#### *Bone Flakes*

Bone flakes can exhibit a platform and a bulb (Fisher, 1995), stress relief marks (Fisher, 1995), greater breath than length (Vetese et al., 2020) and an absence or reduction in cortical bone (Vetese et al., 2020), however as indicated by Fisher (1995) some of the bone flake characteristics can be missing. Both assemblages were surveyed for bone flakes using an incandescent lightbulb. Figure 12 shows typical bone flakes produced by cave roof fall, while

Figure 13 shows bone flakes produced by hammerstone-on-anvil percson. Each bag was emptied on a foam piece. Any small bags inside of the larger bags were emptied out as well. The criteria used to identify bone flakes from each assemblage was described above and modelled after Fisher (1995) and Vetteese et al. (2020). All identified bone flakes that were counted.

*Figure 12 Bone flakes created by cave roof fall*

*Figure 13 Bone flakes created by hammerstone-on anvil percussion*

*Incipient notches, Notches, and Pseudo-Notches*

**Table 7:** Notch Variations and Pseudo Notches Definitions

| Class        | Notch Type                   | Description   | Measurements possible                                    | Source   |
|--------------|------------------------------|---|--|--|
| Notch        | Complete                     | Notch has two inflection points present and no overlapping flake scar         | All  | (Capaldo & Blumenschine, 1994)                         |
| Notch        | Incomplete Type A            | Notch is missing one or both inflection points                                | Notch Depth (Usually)<br>Platform Angle                  |  |
| Notch        | Incomplete Type B            | Notch is missing the flake scar   | Notch Breadth (Occasionally)                             |  |

| Notch        | Incipient/<br>Adherent notch | Notch still has an attached flake or multiple flakes                          | Notch Breadth<br>Notch Depth                             | (Capaldo & Blumenschine, 1994;<br>Vetese et al., 2020) |
| Notch        | Biface                       | Flake scar is present on both cortical and medullary surface                  | Notch Breadth (Usually)<br>Flake Scar Breadth            |  |
| Pseudo notch | Inverse Flake Scar           | Flake scar is present on cortical surface only                                |  | (Capaldo & Blumenschine, 1994)                         |
| Pseudo notch | Incomplete Type D            | Notch is limited to the cortical surface of the bone                          | N/A  |  |
| Pseudo notch | Micro                        | Miniature notches present on the cortical surface. Can be clustered together. |  | (Capaldo & Blumenschine, 1994;<br>Vetese et al., 2020) |

Definitions adapted from Capaldo & Blumenschine (1994) and augmented with definitions from Vetese et al. (2020)

Figure 14 Incipient notch created by cave roof fall

Figure 15 Incipient notch created by hammerstone-on-anvil percussion

Incipient flakes and notches can be described as having a similar arcuate shape as normal notches, but with an incomplete or superficial fracture front and a flake that is still attached to the bone shaft (Vetese et al., 2020). Figure 14 shows an example of an incipient notch in a cave roof fall assemblage, while Figure 15 shows an example of an incipient notch in the hammerstone-on-anvil assemblage. All bone fragments from both assemblages were surveyed for incipient notches underneath an incandescent lightbulb. Individual bags were emptied on foam mats. Smaller fragment bags that were inside a larger bag were emptied as well. When an incipient notch was found it was marked with an arrow pointing away from the incipient notch. These BSM were then numbered with a “N1” for the first one, “N2” for the next one and so on. This numbering convention was reset for each bone surveyed.

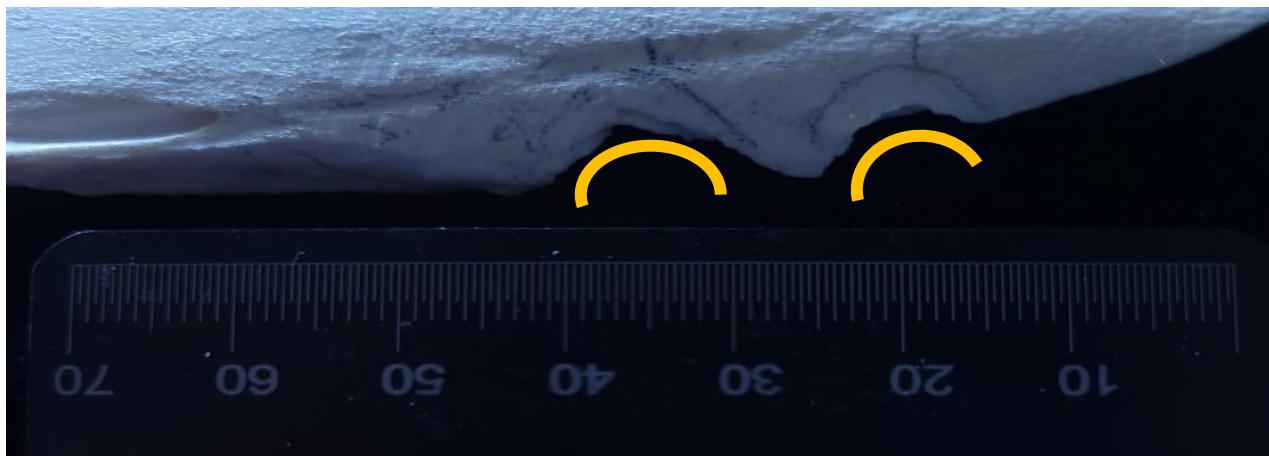

Figure 16 Percussion notch on the cortical side of the fragment

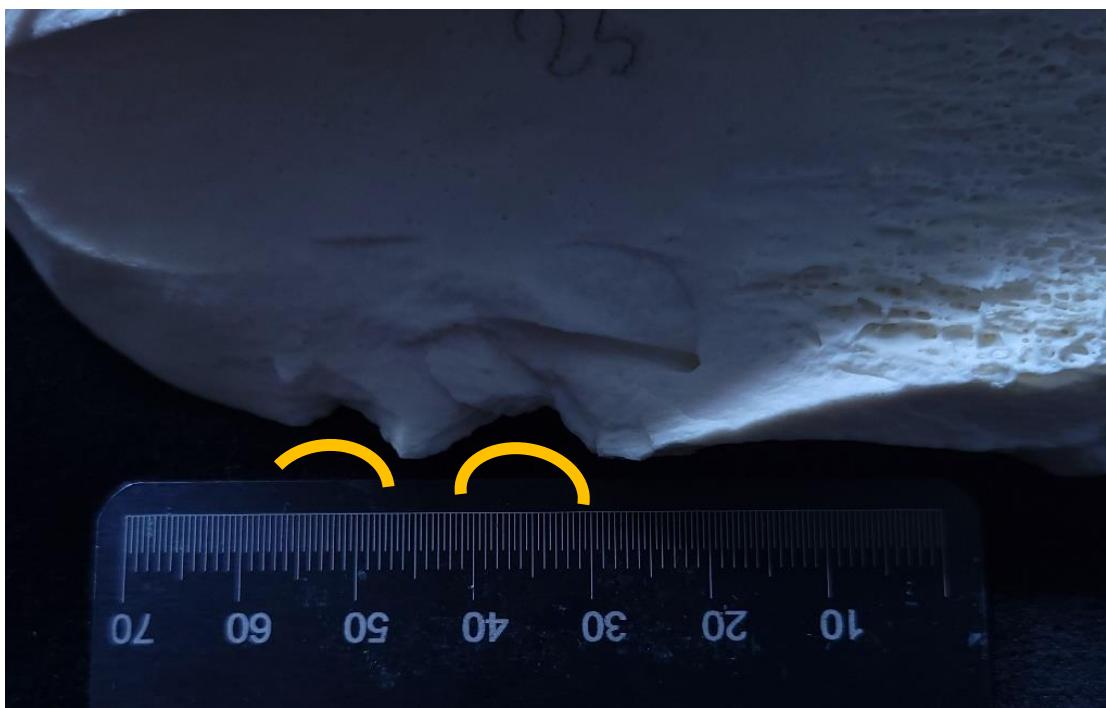

Figure 17 Percussion notch on the medullary side of the fragment

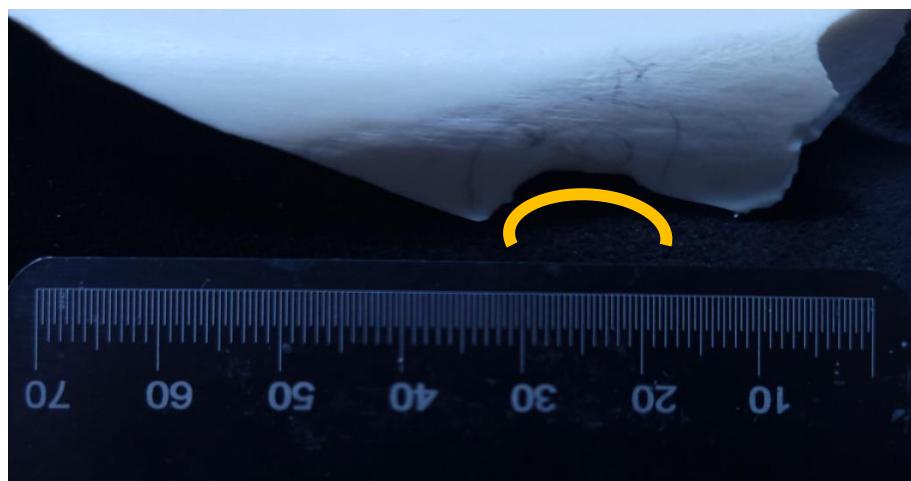

Figure 18 Impact notch on the cortical side of the fragment

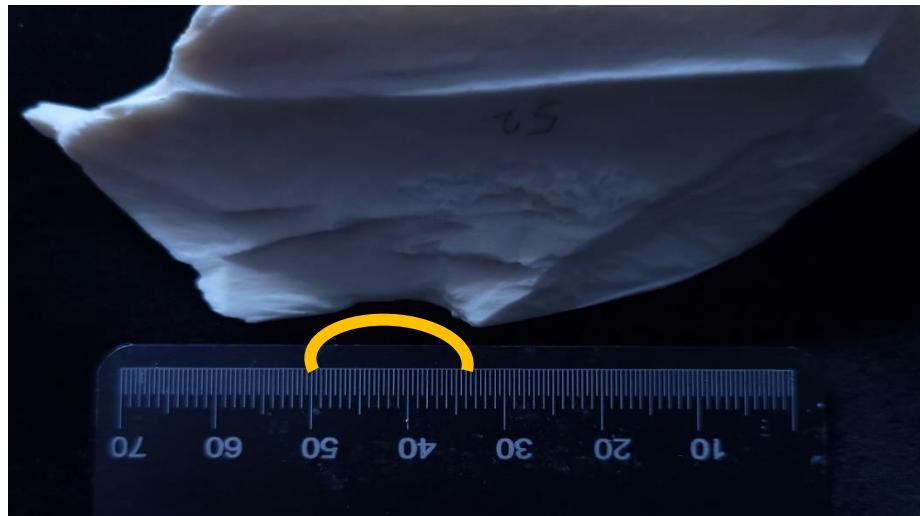

Figure 19 Impact notch on the medullary side of the fragment

Notches are a form of bone surface modification trace that was recorded (see Gifford-Gonzalez, 1991). The criteria used to identify notches is as follows: notches need to be arcuate or semi-lunar, (Vettese et al., 2020), both inflection points need to be present, and the notch needs to penetrate the medullar cavity (Capaldo & Blumenschine, 1994). A count of all notches in each assemblage was carried out. All fragments were emptied out of a single bag. If a smaller bag was inside of a larger bag, the smaller bag was emptied as well. All fragments were surveyed for notches using an incandescent lightbulb as suggested by Blumenschine et al. (1996). Figures 16 and 17 show an example of a percussion notch from both the cortical side of the fragment and the medullary side of the fragment. Figures 18 and 19 show examples of an impact notch from both the cortical side and the medullary side of a fragment. When a notch was found it was marked by a semi-circle. A roman numeral was assigned to the first notch that was identified. The numbering system was reset for each bone.

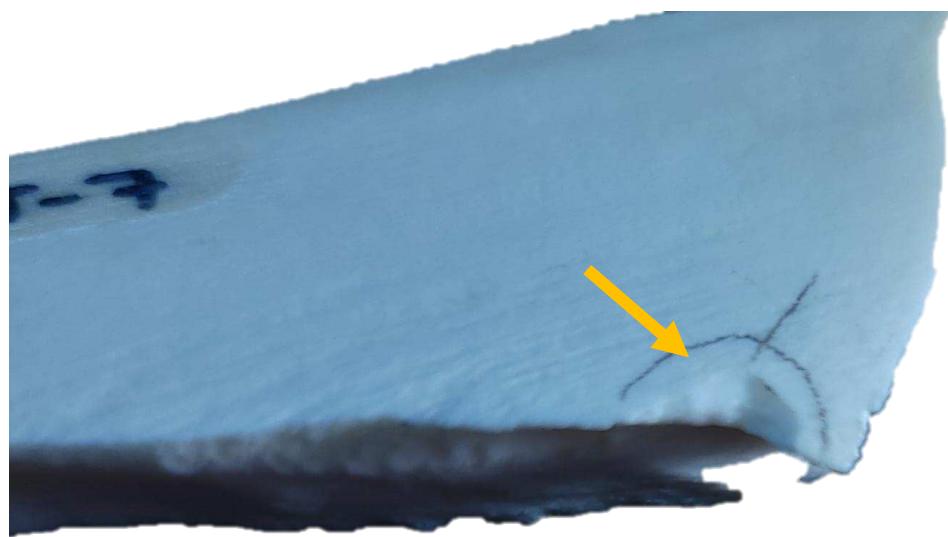

Figure 20 Pseudo-notch on the cortical side of a cave roof fall fragment

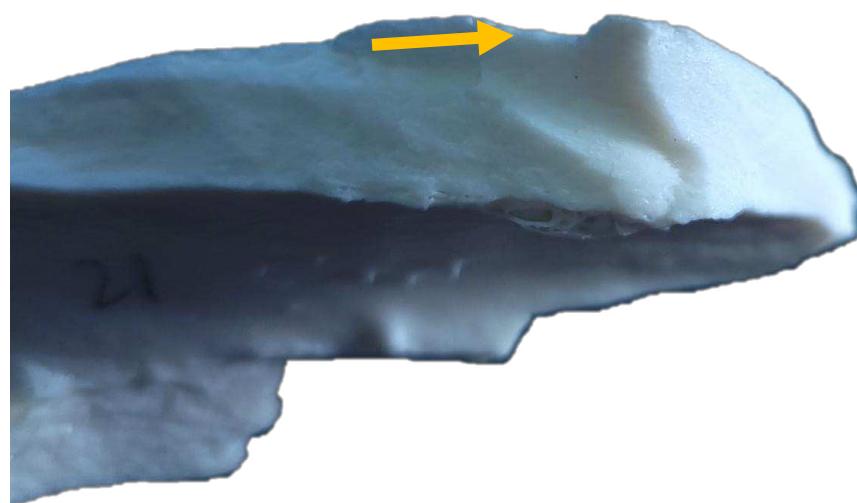

Figure 21 Pseudo-notch on the internal part of a cave roof fall fragment. Note: The pseudo-notch does not penetrate the medullary cavity.

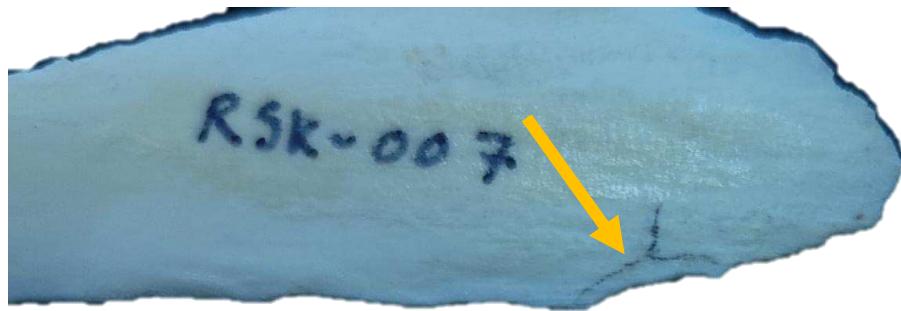

Figure 22 Pseudo-notch on the cortical side of a hammerstone-on-anvil fragment

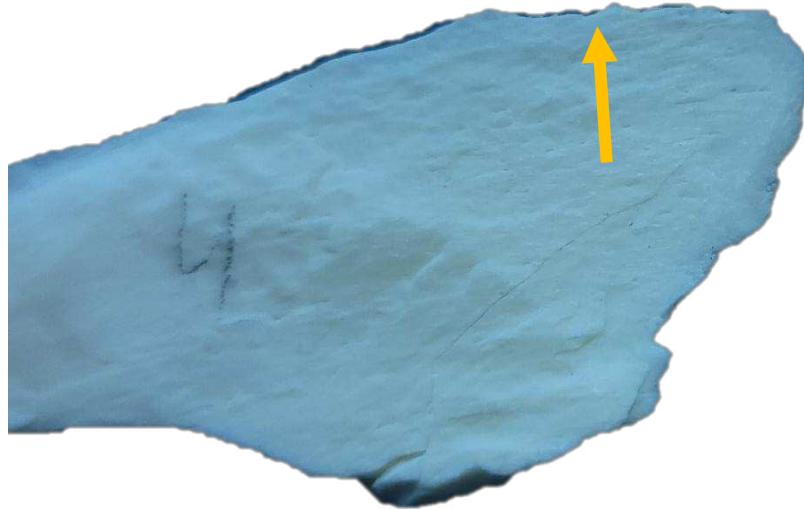

Figure 23 Pseudo-notch on the medullary side of hammerstone-on-anvil fragment

Pseudo-notches appear like notches but do not exhibit any of the criteria applied to notches. Pseudo-notches were counted and placed as a separate variable. All fragments were emptied out of a single bag. If a smaller bag was inside of a larger bag, the smaller bag was emptied as well. All fragments were surveyed for pseudo-notches using an incandescent lightbulb as suggested by Blumenschine et al. (1996). When identified pseudo-notches were marked with a semicircle with a dash in the middle. Figures 20-23 show examples of pseudo-notches on the cortical and medullary sides of fragments in both samples. Table 7 provides a summary of notch types and pseudo-notch types.

*Fragments with cortical surface*

*Figure 24 Fragments with a cortical surface on the left, fragments without cortical surface on the right*

Fragments with cortical surface can be defined as pieces of bone that still have the tough durable outer layer of bone. The cortical layer on bone fragments is also important because BSMs are imprinted and persevered on it (Blumenschine & Selvaggio, 1988; Capaldo & Blumenschine, 1994). A count of fragments with an intact cortical surface was carried for both assemblages. All fragments were emptied out of a single bag on a foam pad to be surveyed. If a smaller bag was inside of a larger bag, the smaller bag was emptied as well. Fragments that have a cortical layer, but not a medullary cavity were still grouped with the fragments that had both. Fragments that did not have any cortical layer left were excluded and not counted. Figure 24 indicates this division, with fragments that do preserve a cortical surface on the left and fragments that do not preserve a cortical surface on the right. This distinction was made because

counting fragments that do not have an intact cortical layer would inflate the overall number of possible fragments that could have a BSM.

*Fragments with pits and grooves*

*Figure 25 Fragments with pits and/or grooves above, fragments without any pits on the bottom*

This count is the number of bone fragments that exhibit at least a pit, a groove or both.

Pits and grooves were put in the same category in this regard because they are created by similar processes, and could be indicative of the same effector (Blumenschine & Selvaggio, 1988; Vettese et al., 2020). A visual survey was carried out on all bone fragments from both assemblages underneath an incandescent light. All bone fragments belonging to a bag were emptied out on a foam pad. If a smaller bag was present in the larger bag, it was emptied out as well. All fragments that exhibited a pit and/or groove were separated and then counted for a total.

Figure 25 shows this division, with fragments that exhibit a pit and/or groove on top, and fragments that do not exhibit a BSM on the bottom.

#### *Fragments with notches*

The number of fragments with notches is a count that recorded the number of bone fragments that exhibit at least one notch. All bone fragments from the cave roof fall and hammerstone-on-anvil assemblage were surveyed. The bone fragments belonging to a specific bag were emptied out on a foam mat. If a smaller fragment bag was present in the larger bag, it was emptied out as well. If at least one notch was identified on a fragment, it was put aside. Any additional afflicted fragments from the same bag were also placed in the same group. A count of fragments afflicted by notches was then carried out. All bone fragments were surveyed underneath an incandescent lightbulb.

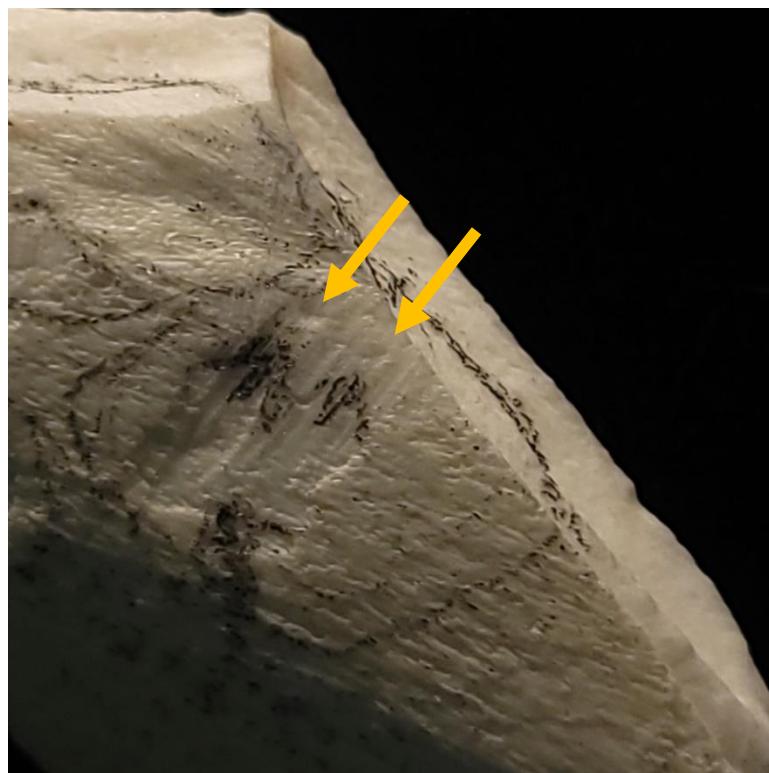

#### **3.3.2 Visual - With Magnification**

Percussion marks as described in Blumenschine & Selvaggio (1988) were identified using magnification. To investigate the relationship between percussion marks left by hammerstone-on-anvil percussion and the analogous traces left by cave roof fall, percussion marks were split into pits, grooves and striations as described in White (1992). This separation was also carried out for the analogous traces left by cave roof fall. The decoupling of pits, grooves and striations from percussion pits is done with the understanding that these traces are created through similar processes and are part of the same trace complex (Pickering & Egeland, 2006).

*Pits*

*Figure 26 Impact pits indicated by the arrows*

*Figure 27 Percussion pits indicated by the arrows*

A survey of all bone fragments in both assemblages was carried out using an incandescent light a 3x magnifying glass and a 10x hand lens as described in Blumenschine et al. (1996). All bone fragments were emptied out of a single bag. Smaller bags that were within the large bag were emptied out as well. The fragments were placed on a foam mat. Pits were counted if they conformed to the following criteria: pits had to be imprinted in the cortical layer of the bone (Blumenschine & Selvaggio, 1988), pits had to be deep, round and either exhibit microstriations or radiate microstriations (Blumenschine & Selvaggio, 1988). When an impact pit (Figure 26) or percussion pit (Figure 27) was identified an arrow was drawn pointing to the pit.

#### *Grooves*

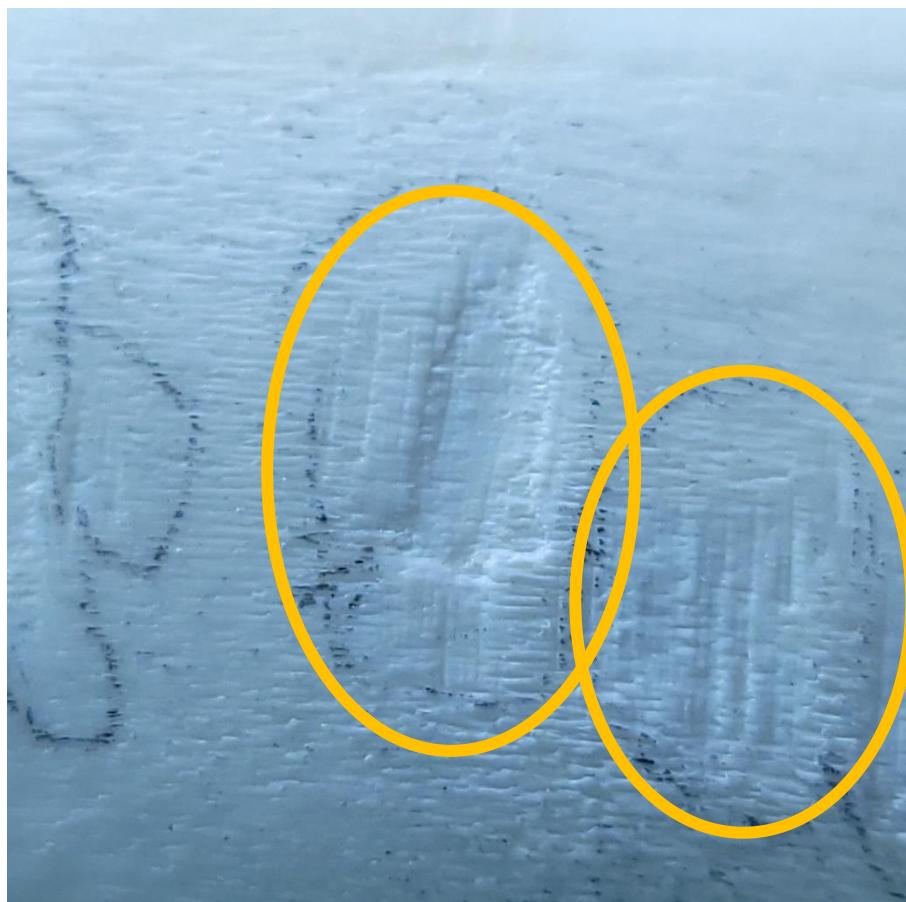

*Figure 28 Impact groove*

*Figure 29 Percussion groove*

Grooves are a BSM that was recorded (see Gifford-Gonzalez, 1991). Grooves can be described as a pit that has been stretched out. The criteria by which grooves were selected was as follows: the groove had to be located on the cortical surface of the bone (Blumenschine et al., 1996), the groove had to be elongated (Vettese et al., 2020) and the groove had to exhibit microstriations or radiate microstriations (Blumenschine & Selvaggio, 1988). All bones from the cave roof fall assemblage and the hammerstone-on-anvil percussion assemblage were surveyed. The fragments were each taken out of their bag and placed on a foam mat. If smaller bags were within the larger bag, the smaller bags were emptied out as well. All bone fragments were surveyed using a 3x magnifying glass 10x magnifying hand lens and an incandescent light bulb as instructed by Blumenschine et al. (1996). All impact grooves (Figure 28) and percussion grooves (Figure 29) that were identified were marked with an arrow that had a dash through it.

*Striations*

*Figure 30 Impact striations*

*Figure 31 Percussion striations*

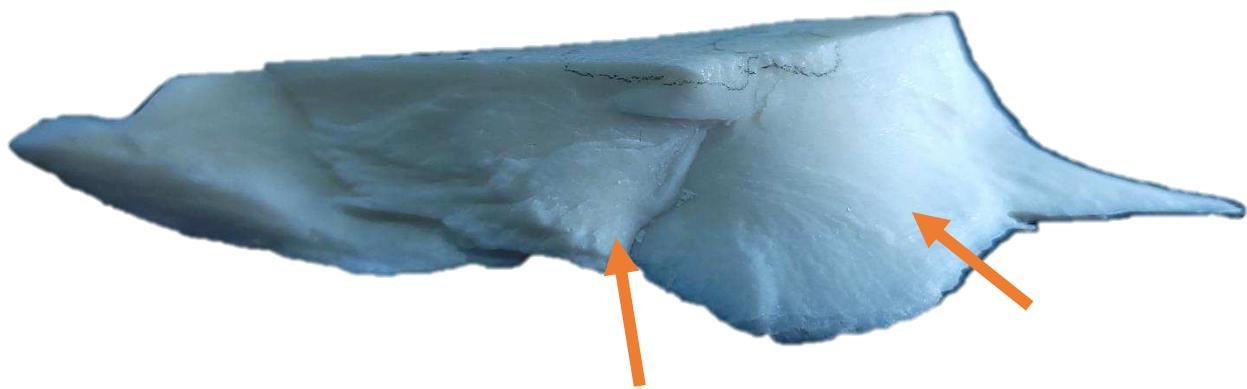

Striations are a BSM that was recorded. Striations can be described as parallel superficial scratches on the cortical surface of the bone that appear in patches (Blumenschine & Selvaggio, 1988). Examples of both striations created by both actors can be seen in Figure 28 and 29. All bone fragments in the cave roof fall assemblage and in the hammerstone-on-anvil assemblage were visually surveyed. All bone fragments belonging to a bag were emptied out on a foam pad. If a smaller bag was inside the larger bag, the smaller bag was emptied out as well. Striations were identified using a 3x magnifying glass for a general survey, a 10x hand lens for proper identification and an incandescent light bulb as described in Blumenschine et al. (1996). When

striations were found a circle was drawn around the striations. After all striations were identified a count was carried out for a total.

### ***3.3.3 Presence/Absence***

#### *Hackle marks and Ribs*

Hackle marks and ribs are traces associated with dynamic loading. Hackle marks can be seen in Figure 32 and Figure 34 while ribs are in Figure 33 and Figure 35. Both traces were treated as separate variables and given individual columns. All the bone assemblages were surveyed for hackle marks and ribs. A simple absence/presence observation was used per assemblage. If one fragment exhibited hackle marks then the whole bone assemblage was marked with a “Yes”. If no hackle marks were found the whole bone assemblage was marked with a “No”. A similar technique was employed for ribs, with a “Yes” assigned to a whole bone assemblage if a rib was found on a fragment, and a “No” assigned if no ribs were found on any fragments within a bone assemblage.

*Figure 32 Hackle marks on cave roof fall created fragment*

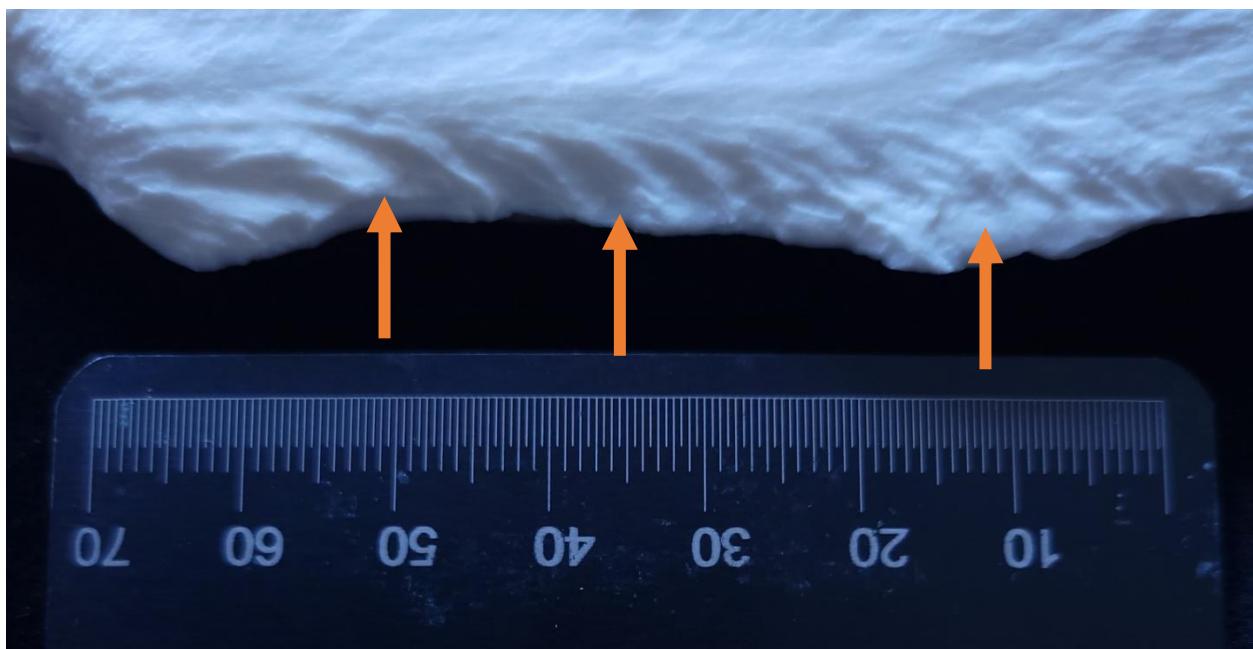

Figure 33 Ribs on a cave roof fall created fragment

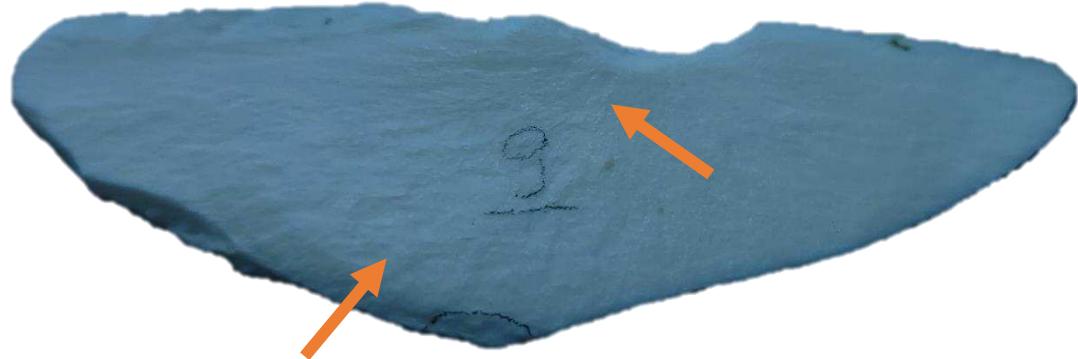

Figure 34 Hackle marks on a hammerstone-on-anvil created fragment

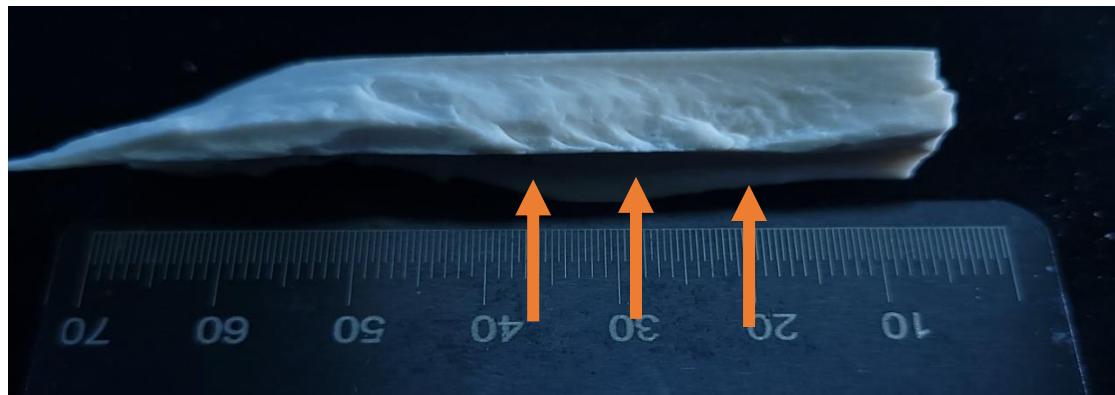

Figure 35 Ribs on a hammerstone-on-anvil created fragment

Hackle marks and ribs were recorded to verify that dynamic impact is the causal agent for both cave roof fall and hammerstone-on-anvil percussion (Gifford-Gonzalez, 1991). If the cave roof fall assemblages exhibit hackle marks and ribs on at least one bone in each assemblage then it can be inferred that cave roof fall ruptures the diaphysis through dynamic loading like hammerstone-on-anvil percussion. If only some of the cave roof fall bone assemblages exhibit hackle marks and ribs then doubt is cast on dynamic impact as the causal agent for cave roof fall.

### **3.3.4 Measurements**

*Figure 36 Digital caliper used to measure fragments longitudinally*

Linear measurements were done in centimeters using a caliper as seen in Figure 36 and a measuring tape for larger fragments as seen in Figure 37. Fragment size and epiphysial element length was measured in both assemblages. Linear measurements were taken longitudinally to the long axis of the bone. For fragments that detached from the shaft the long axis of the bone was established by observing the general orientation of the cortical bone, which is longitudinally oriented. Notch dimensions were obtained in centimeters by using a caliper to measure molds pressed into notches to form the missing flake. Release angle was measured in degrees using a goniometer.

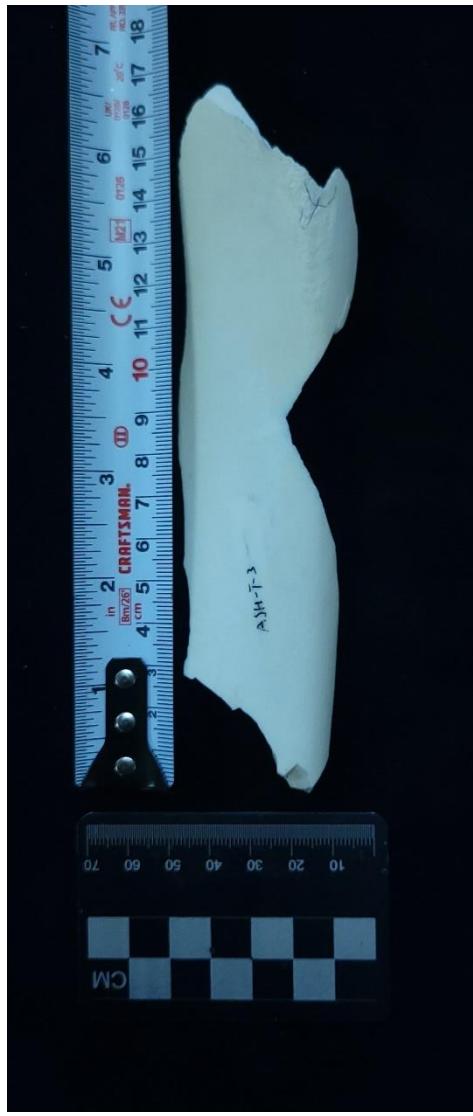

Figure 37 Tape measure used to measure large fragments longitudinally

*Fragment size categories*

*Figure 38 Example of fragments under 2 cm from a cave roof fall assemblage*

*Figure 39 Example of fragments between 4 and 4.99 cm from a cave roof fall*

Ten size categories were created to accommodate the variety of fragments that are produced during shaft fragmentation with some examples illustrated in Figure 38 and 39. The

size categories are fragments smaller than 2 cm, 2-2.99 cm, 3-3.99 cm 4-4.99 cm, 5-5.99 cm, 6-6.99 cm, 7-7.99 cm, 8-8.99 cm, 9-9.99 cm and larger than 10 cm. The bone fragments were not presented as individual measurements because the individual dimensions of the bone fragments would be less informative than the number of fragments in each dimension category. The measurement intervals were created based on the example provided by Capaldo & Blumenschine (1994). Fragments smaller than 2 cm represents small fragments, such as chips, and some flakes. Fragments in between 2 cm and 9.99 cm represent medium sized fragments, like some flakes, or complete parts of the diaphysis. Fragments larger than 10 cm are usually large fragments that survived fragmentation such as epiphyseal elements and intact shaft fragments.

All bone fragments including epiphyseal elements, were measured, and then placed in their respective category. This was done for both assemblages. A bag containing the fragments of one bone assemblage was emptied out on a foam pad. If a smaller bag was inside the larger bag, the smaller bag was emptied out as well. A caliper was used to measure fragments that were of appropriate size. The caliper was extended past the size of the fragment, and then the adjustable part was pushed until it contacted the fragment as seen in Figure 34. The measurements were produced in millimeters but were recorded in centimeters. After the measurement was recorded, the adjustable part was pushed back to zero and the caliper was reset to prevent mismeasurements. If a measurement exceeded the capabilities of the caliper, a tape measure was used. The tape measure was unfurled and the fragment was placed adjacent to the metric scale. Measurements were recorded in centimeters, with millimeters to the nearest tens decimal point. To obtain the percentage that a size category contributed to the overall fragment number of an actor, a size category was summed up and then divided by the total fragment number. The quotient was then multiplied by 100 (see Appendix Table 24).

### *Epiphyseal Element Measurements*

Epiphyseal element length was recorded. Epiphysial elements are the articular ends of a bone usually made up of trabecular bone. In the case of the tibial bones used, the proximal epiphysial element connected to the distal epiphysial end of the femur, and the distal epiphyseal element of the tibia connected to the astragalus bone (talus in humans). All epiphysial elements from both assemblages were visually surveyed and measured. Measurements were split into two categories, the distal epiphyseal element, and the proximal epiphyseal element. Measurements were done using a digital caliper or a measuring tape. Measurements were taken from the metaphyseal line to the longest part of the fragment as indicated by the orange lines in Figures 40-43. The metaphyseal line was used as a measuring point instead of the actual epiphysis because of the following reasons. For almost all bones in both samples the proximal epiphysis was removed. This either happened during boiling as part of bone processing, or it was removed to curb mold and bacterial growth as seen in Figure 40. The other reason for the use of the metaphysis over the epiphysis as a measurement point was because in the hammerstone-on-anvil sample the distal epiphysis became detached as well as seen in Figure 43. Measurements would be inconsistent if the distal epiphysis was present for some elements and not others.

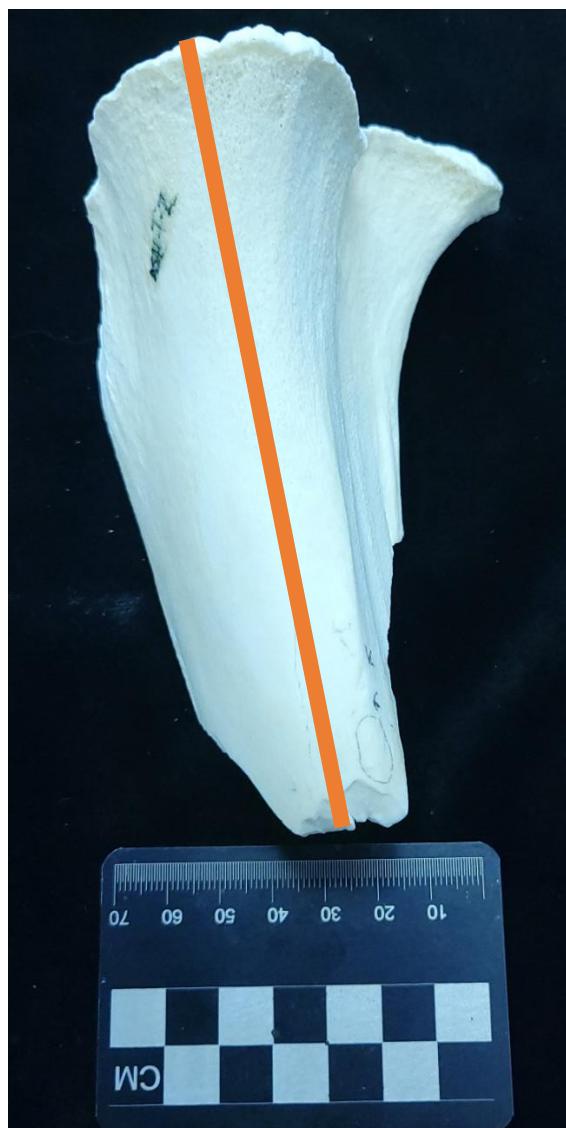

Figure 40 Proximal epiphysial element

Figure 41 Distal epiphysial element with a fused metaphysis

Figure 42 Distal epiphysial element with an unfused metaphysis

Figure 43 Distal epiphysial element without an epiphysis

### Notch dimensions

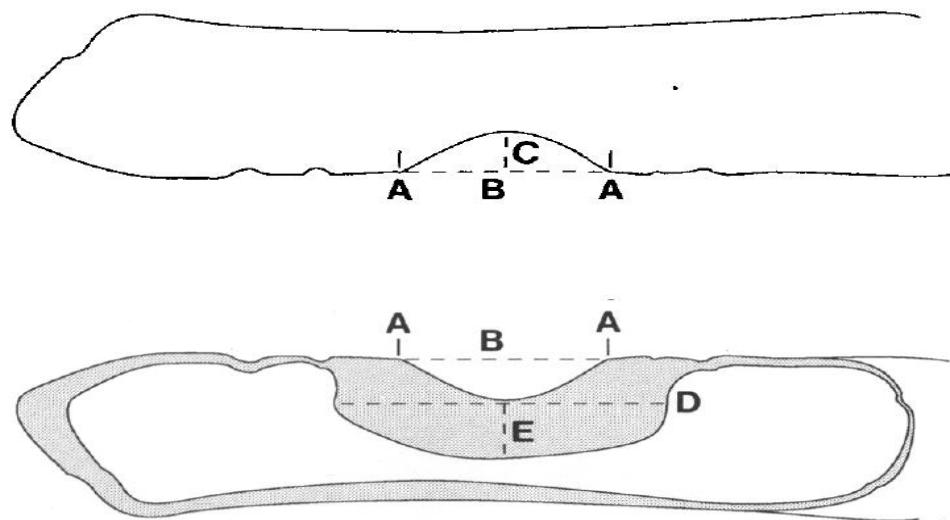

Figure 44 Figure shows notch breadth (A), halfway point of notch breadth (B), notch depth (C), flake scar breadth (D) and flake scar depth (E). From *A Quantitative Diagnosis of Notches Made by Hammerstone Percussion and Carnivore Gnawing on Bovid Long Bones* by S. D. Capaldo, & R. J Blumenschine, 1994. American Antiquity, 59(4), p. 733. Copyright 1994 by the Society for American Archaeology.

Notch measurements follows the methodology laid out by Capaldo & Blumenschine (1994). This methodology involves the use of molding putty applied to the percussion notch to recreate the dimensions of the flake and to help define the dimensions of the percussion notch (Capaldo & Blumenschine 1994). The measurements are as follows: maximum notch breadth (Figure 44 A), maximum notch depth (Figure 44 C), maximum flake scar breadth (Figure 44 D), maximum flake depth (Figure 44 E), and platform angle. Maximum notch breadth was measured by marking the inflection points of the notch on the cortical side of the fragment on the putty and then measuring the distance between the two points. The breadth also informed the measurement of the maximum notch depth, which was measured from the middle of the notch breadth towards the cortical bone. The flake scar breadth and flake depth were gathered from the medullary part of the mold, with the flake scar breath measured at the widest part after the cortical surface, and

the flake depth was measured from the beginning of the cortical bone to the beginning of the medullary cavity.

Impressive putty© was used to create molds of the identified notches in both the cave roof fall sample and in the hammerstone-on-anvil sample. The molding material was heated up in a microwave to make it malleable. After it was kneaded chunks of the putty were pressed into the notches to create a notch mold. Care was taken to spread the molding material fully between inflection points and to completely cover the flake scar. After the molding material was set the bone was left in a refrigerator for 15 minutes for the molding material to harden. Once 15 minutes elapsed the bone was taken out and the molding material was measured. A line was drawn on the hardened molding material connecting the two inflection points delineating the notch breadth as seen in Figure 44 A. A ruler was used to find the middle of the notch breadth as seen in Figure 44 B. From this middle point a straight line was drawn towards the notch, which would be the notch depth as indicated by Figure 44 C. Both notch breadth and notch depth were measured using digital calipers. Notch breadth and notch depth were also measured from incipient flakes in a similar manner, but without using putty, since the flake itself was still present. Once notch breadth and notch depth were measured the molded flake was removed to measure flake scar breadth as shown in Figure 44 D. Flake scar breadth was measured using a digital caliper. Flake scar breadth was not collected from incipient flakes because the body of the flake prevented such measurement. The roman numerals assigned for each notch were transferred to the notch measurements. As indicated by Capaldo & Blumenschine (1994) these measurements are not diagnostic of notch qualities, but rather the ratios build from these variables are descriptive of notch qualities.

### *Release angle*

Release angle of the platform angle is defined as the angle at which the flake detached from the diaphysis forming a notch (Capaldo & Blumenschine, 1994). To measure the release angle a goniometer was used. After gathering the notch dimensions from the molds created from impressive putty© one arm of the goniometer was placed on the “cortical” top of the mold where notch breadth and notch depth was measured. The other arm of the goniometer was brought towards the “medullary” side of the mold that had the flake scar breadth until it met the farthest part of the medullary mold. The roman numerals assigned for each notch were transferred to the release angle measurements.

### **3.3.5 Composite Variables**

#### *BSM Ratios*

##### Percentage of Cortical Fragments with a Pit or a Groove

The percentage of cortical fragments with a pit or a groove was derived by dividing the number of fragments that exhibit pits or grooves by the total number of fragments that still preserve a cortical surface. Following this division, the ratio was multiplied by 100 to get a percentage. This variable was used to “flatten” two variables, in this case fragments with pits and notches and fragments with a cortical surface into one variable and expose the relationship between the two.

##### Percentage of Cortical Fragments with Notches

The percentage of cortical fragments with notches was derived by dividing the number of fragments that have a notch by the total number of fragments that still preserve a cortical surface. Following this division, the ratio was multiplied by 100 to get a percentage. This variable was

used to “flatten” two variables, in this case fragments with notches and unaffected fragments with a cortical surface into one variable and expose the relationship between the two.

#### Pseudo-Notch to Notch Ratio

The ratio of pseudo-notch to notch ratio was calculated by dividing the number of pseudo-notches in each bone assemblage by the number of identified notches. This was done to generate a “collapsed” variable that portrays the relationship between the two variables.

#### *Notch Ratios*

Capaldo & Blumenschine (1994) used notch breadth, maximum notch depth and flake breadth to form the following ratios: notch breadth : maximum notch depth and flake scar breadth : maximum notch depth. Notch shape was described by notch breadth : maximum notch depth. Flake shape was described by flake scar breath: maximum notch depth. These same ratios were employed to describe the general notch shape and flake shape of impact notches and percussion notches. Notch shape (notch breadth : maximum notch depth) data gathered from incipient notches was combined with the notch shape data recovered from notches.

### **3.4 Hypothesis Testing and Statistics**

#### *Intra Actor*

Throughout the experiment the four trials were kept separate to pick up any differences between the different boulder weights and boulder drop heights. Unfortunately, this is not possible due to the small sample size of 4 bones that was assigned per group. Furthermore, some of variables of interest had fewer than 4 observations due to the lack of data. To remedy this all trials were collapsed into one experiment, cave roof fall. While this action does erase any difference that might have existed between trials, it does introduce variation within the new cave roof fall sample (M. Glantz & M. Pante, personal communication, 2022).

## *Inter Actor*

### Summary Statistics and Graphs

Mean, median, standard deviation were calculated as summary statistics for the twenty nine testable variables collected from the cave roof fall sample and the hammerstone-on-anvil percussion sample. Histograms were created in R Studio for each testable variable in both samples. Violin plots in the vioplot R package were used instead of box plots for better data visualization. Violin plots were utilized because they combine the summary statistics provided by box plots with a visualization of data distribution. Scatter plots were created to visualize variables tested with Spearman's rank order correlation.

### Statistical Tests

Mann-Whitney U test, Spearman's rank correlation and Fisher's exact test were used to evaluate the relationship between variables collected from the cave roof fall and hammerstone-on-anvil percussion samples. These three tests were used to accommodate the different types of data and hypotheses derived from the data. All tested variables and statistical tests that were used are summarized in Table 8. The alpha for all tests was set at 0.05.

The Fisher's exact test (FET) was employed to test the binary response of incipient notches and notches between the cave roof fall sample and the hammerstone-on-anvil sample. This is done by testing the association between each binary response and actor through a contingency table. These two variables were tested using FET because cave roof fall had less than the minimum of 5 observations needed to carry out a Mann-Whitney U test.

Fragment size categories were assessed using Spearman's rank correlation. This test was picked to test if fragment size categories produced by each actors have a monotonic relationship and if so if the correlation is positive or negative. A monotonic relationship between two

variables is when one variable increases the other either decreases or increase as well. The degree to which the variables correlate is provided by the correlation coefficient (between -1 and 1).

All other variables except for fragment count were tested using the Mann-Whitney U test. Fragment count was not tested because bone fragmentation is sensitive to influence from other actors (e.g., sediment pressure, trampling, diagenetic fragmentation) and cannot be applied to archaeological sites. The Mann-Whitney U tests was used because of its versatility to handle multiple types of data (measured, ratios and counts) and because the normality of the data set was called into question by the numerous skewed histograms (see Appendix). This test was used to test for a difference between the cave roof fall and hammerstone-on-anvil percussion. Any variable that had less than 5 observations in any sample was either tested using a different tests (FET or Spearman's rank correlation) or were not tested. This was done because any variable with less than 5 observations per sample will always return a p-value larger than 0.05 (A. Hess, personal communication, 2021).

**Table 8** Statistical Tests with Assigned Variables from Both Assemblages

| Variable   | Test                              |
|--|-----------------------------------|
| Notch count                                      | Fisher's exact test               |
| Incipient notch count                            |                                   |
| Fragment size categories                         | Spearman's rank order correlation |
| Flake count                                      |                                   |
| Pit count  |                                   |
| Groove count                                     |                                   |
| Striation count                                  |                                   |
| Distal element length                            |                                   |
| Proximal element length                          |                                   |
| Percentage of fragments with a pit and/or groove | Mann-Whitney U test               |
| Percentage of fragments with a notch             |                                   |
| Pseudo-notch count                               |                                   |
| Pseudo-notch : notch                             |                                   |
| Notch breadth : maximum notch depth              |                                   |
| Flake scar breadth : maximum notch depth         |                                   |
| Fragments with a cortical surface                |                                   |
| Fragments with a pit and/or grooves              |                                   |
| Fragments with a notch                           |                                   |
| Release angle                                    |                                   |

### Hypotheses and Predictions

For each test employed a pair of hypotheses were created to test each assigned variable.

Prediction (see Table 9) were made to about each variable, how each variable might interact with each actor and why.

#### ***Fisher's Exact Test:***

**H<sub>0</sub>:** The binary response of this variable is not different for both samples

The null hypothesis will be considered if there is no difference (p-value > 0.05) in the variable binary response for the cave roof fall and hammerstone-on-anvil percussion sample.

**H<sub>1</sub>:** The binary response of this variable is different for both samples

The alternative hypothesis will be viable if there is a significant difference (p-value < 0.05) in the variable binary response for both samples.

### ***Spearman's rank correlation:***

**H<sub>0</sub>:** The relationship between these two variables is not monotonic.

The null hypothesis will be feasible if the compared variables from each actor are not monotonic (p-value > 0.05).

**H<sub>1</sub>:** The relationship between these two variables is monotonic.

The alternative hypothesis will be considered if there is enough significant evidence (p-value < 0.05) that the variables are monotonic.

### ***Mann-Whitney U test:***

**H<sub>0</sub>:** There is no difference between cave roof fall and hammerstone-on-anvil percussion.

The null hypothesis will be viable if the variable tested does not point to a significant difference (p-value > 0.05) between cave roof fall and hammerstone-on-anvil percussion.

**H<sub>1</sub>:** There is a difference between cave roof fall and hammerstone-on-anvil percussion.

The alternative hypothesis will be considered if the tested variable point towards a significant difference (p-value < 0.05) between cave roof fall and hammerstone-on-anvil percussion.

**Table 9** Predictions for the Outcome of each Tested Variable for Each Actor

| Variable              | Prediction   | Visual |
|-----------------------|--|--------|
|                       |  |        |
| Flake count           | <ul style="list-style-type: none"><li>-Higher energy transfer into the diaphysis by roof fall impact creates more impact flakes</li><li>-Wider blow distribution along the diaphysis by hammerstone-on-anvil percussion creates more percussion flakes</li></ul>   |        |
| Incipient notch count | <ul style="list-style-type: none"><li>-More energy radiating from roof fall impact site through the diaphysis creates more impact Incipient notches</li><li>-Smaller diaphyseal surface area affected by roof fall creates less impact incipient notches</li><li>-Wider blow distribution along the diaphysis by hammerstone-on-anvil percussion creates more percussion incipient notches</li></ul> |        |

| Notch breadth : Maximum notch depth              | <ul style="list-style-type: none"> <li>-Cave roof fall will create “hyper” arcuate notches with a higher notch breadth to notch depth ratio than those created by hammerstone-on-anvil percussion</li> </ul>  |
| Flake scar breadth : Maximum notch depth         | <ul style="list-style-type: none"> <li>-Cave roof fall will create thinner flakes with a larger flake scar breadth to notch depth ratio than those created by hammerstone-on-anvil percussion</li> </ul>  |

## CHAPTER IV: RESULTS

The purpose of this actualistic experiment is to differentiate between cave roof fall and hammerstone-on-anvil percussion. The need for a differentiation between the two actors has been brought up by multiple researchers (Capaldo & Blumenschine, 1994; Dixon, 1984; Oliver, 1989). However, despite this need, only Karr & Outram (2012) have looked at cave roof fall from an actualistic perspective. The lack of research into cave roof fall as a modifier of bones has created a hole in the taphonomic literature and the appearance of an equifinality between the actors. The results from the cave roof fall experiment and its comparison with hammerstone-on-anvil percussion will be presented here. Before the results are presented, the research question with accompanying hypotheses will be restated as a refresher, along with the tests used to answer this research question and their supporting hypotheses as seen in table 10.

**Table 10** Reaserch Question with Hypotheses and Statistical Tests with Hypotheses

## 4.1 Experimental Results

**Table 11** Summary Statistics for Number of Blows Attributed to Cave Roof Fall to Fracture the Bison Tibiae

|        | Number of blows for bone fracture |
|--------|-----------------------------------|
| Mean   | 1.75                              |
| SD     | 1                                 |
| Median | 1                                 |

All sixteen bison tibiae were broken during the experiments. This means that a rock that weights at least 6.8 kg that is dropped from 4.6 m will likely produce bone breakage. On average 1.75 blows were needed to fracture the diaphysis of the bison tibiae. This average only considers the times the boulder contacted bone as opposed to the number of overall trials. The standard deviation is 1, while the median is 1. The summary statistics of the cave roof fall experiments can be seen in Table 11. A more detailed table can be found in the Appendix. Three of the four rocks used survived the experiment. Rock 1 fractured as soon as it impacted the bone. To carry on the experiment Rock 3 was used as a replacement. Rock 3 was the same weight as Rock 1 and of similar shape and dimensions.

**Table 12** Summary Statistics for Number of Blows Attributed to HAP to Fracture the Bison Tibiae

|        | Total number of blows for bone fragmentation |
|--------|--|
| Mean   | 21.9   |
| SD     | 5.5  |
| Median | 23.5   |

Copyright 2019 by Stavrova et al.

The data associated with the creation of the hammerstone-on-anvil sample was unavailable. To compensate Stavrova et al. (2019) was used as a proxy for the hammerstone-on-anvil data. The study uses ten tibiae, which while less than the sixteen tibiae selected from the assemblage, is still informative about the blows necessary to fracture the diaphysis. As summarized in Table 12, the mean blows necessary to break the diaphysis is 21.9. The standard deviation of the hammerstone-on-anvil sample is 5.5 and the median is 23.5. Overall cave roof fall breaks the tibial epiphysis with less blows than hammerstone-on-anvil percussion.

#### **4.2 Data Distribution and Summary Statistics**

The data for all collected variables is depicted as histograms in the Appendix under Histograms. This was done to illustrate the distribution of each variable. Some of the histograms that diverge from the normal distribution will be presented here. Most of the variables tend to skew right. The tendency of the data to skew to the right is related to the abundance of zeros generated by using counting as a data-gathering technique. A few variables have closer to a normal distribution, as seen in Figure 45. Of the Hammerstone-on-anvil percussion (HAP) variables the fragments count, distal element length, fragments with percussion pit count, and cave roof fall striation count are closer to a normal distribution. These variables likely have a more normal distribution because the data collected does not have many zeros and is more evenly spaced out, as opposed to aggregating around specific values as seen in left and right skewed data.

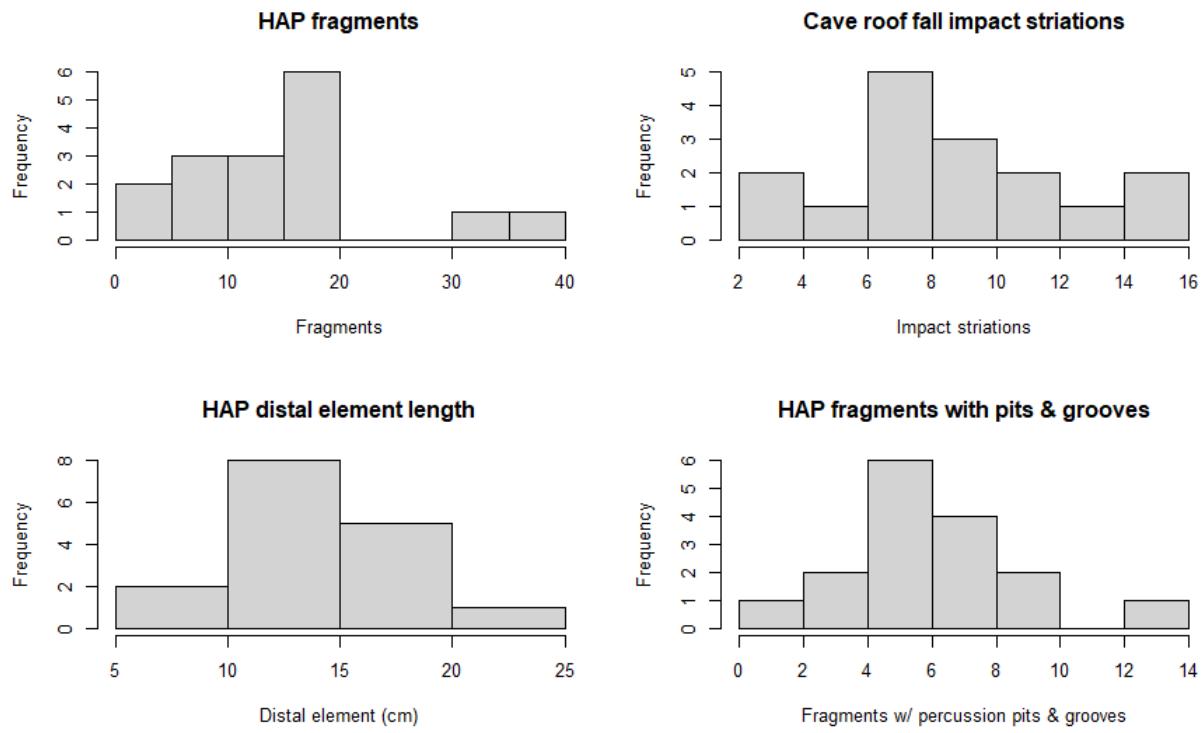

Figure 45 Normally distributed variables. HAP is hammerstone-on-anvil percussion

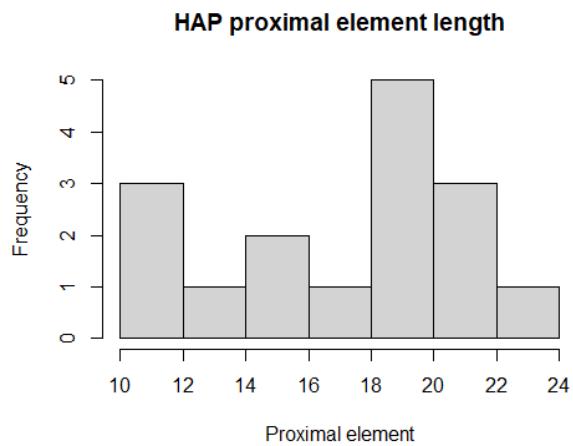

Figure 46 Histogram of left skewed data

Hammerstone-on-anvil percussion proximal element length is the only variable that is skewed left (see Figure 46). This skew might be an artifact and related to the direction of percussion blows. If the first blow started roughly in the middle of the diaphysis and then traveled towards the distal end of the bone then the proximal end would be larger. This is supported by the somewhat normal distribution seen in the distal element histogram in Figure 45. A normal distribution means that there is a wider range of values which implies that the values are not clustering around a specific value as seen in Figure 46.

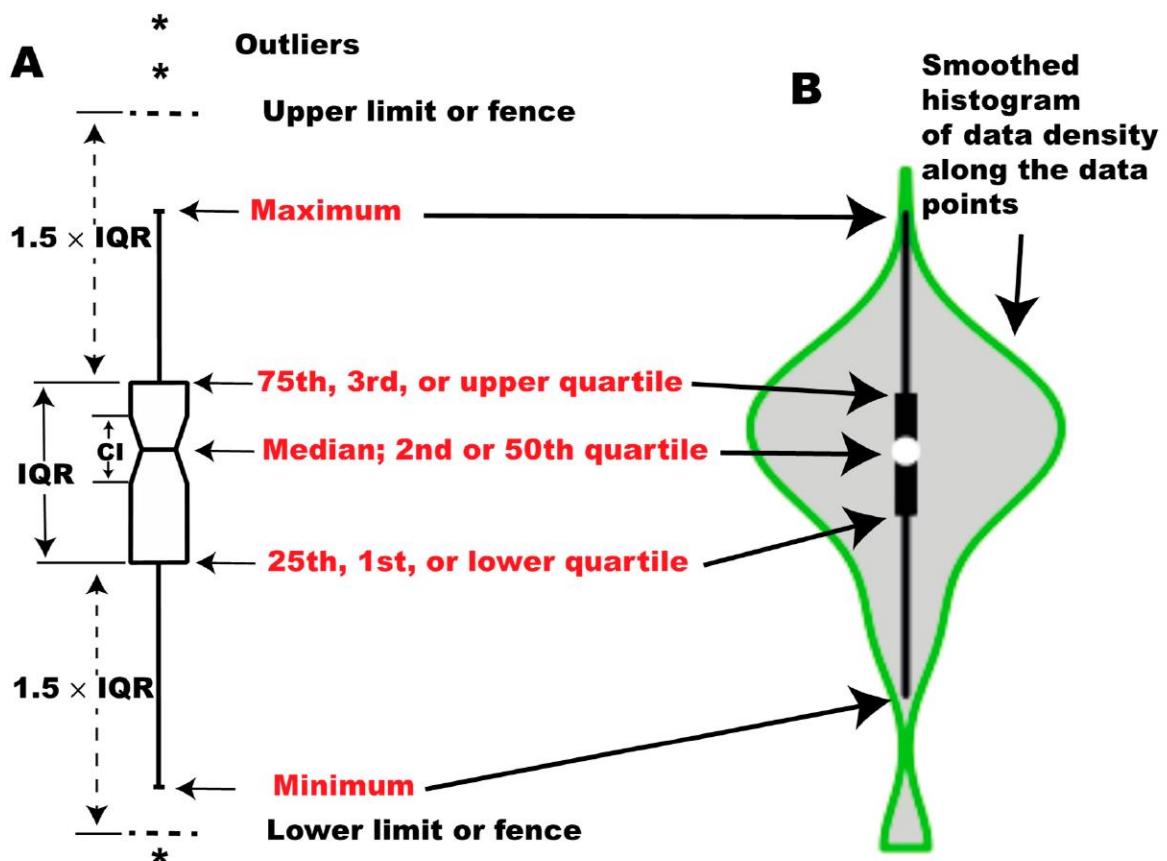

Figure 47 Anatomy of a violin plot. Source: "Become Competent within One Day in Generating Boxplots and Violin Plots for a Novice without Prior R Experience" by K. Hu, 2020 The Methods and Protocols, 64(3), p. 3. Copyright 2020 by the author

Violin plots were used to visually represent the information from Table 13 and provide a side by side comparison of the two actors. As seen in Figure 47, violin plots depict the median, the quartile range, the range, and the general density of values. The violin plots for all the variables can be found in the Appendix under Violin Plots. Most of the variables in both data sets are shown to have overlapping medians upper/lower adjacent values. Violin plots of variables that proved to be statistically different will be presented in the result section. The summary statistics presented in Table 13 are the mean, standard deviation (SD) and median.

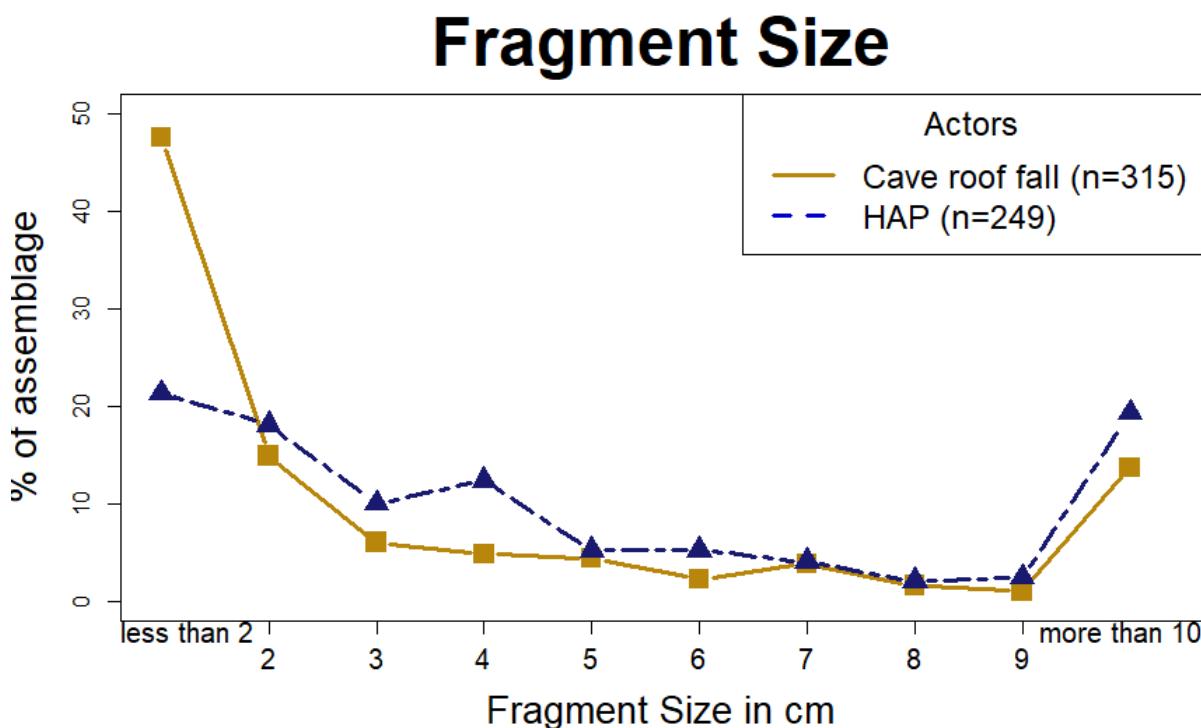

Figure 48 Fragment size distribution in relation to the assemblage

**Table 13 Summary Statistics for Each Collected Variable**

| Actor                           | Fragment count   | Incipient notch count | Flake count                    | Notch count                    | Pit count                       | Groove count                    | Striation count                            | Fragments <2 cm                                  | Fragment 2-2.99 cm | Fragment 3-3.99 cm          | Fragment 4-4.99 cm           | Fragment 5-5.99 cm                | Fragment 6-6.99 cm | Fragment 7-7.99 cm | Fragment 8-8.99 cm |            |            |

|                                 | Median           | 0.0                   | 3.0                            | 13.4                           | 18.8                            | 14.0                            | 6.0  | 0.5  | 0.5                | 0.0                         | 3.5                          | 0.0                               | 4.4                | 6.81               | 36.0               |            |            |

### 4.3 Statistical Test Results and P-values

The results from all tests are reported here. The combined results from each statistical test are presented individually with all tested variables.

#### *Fisher's Exact Test*

**Table 14** P-values from Fisher's Exact Test for Notch and Incipient Notch Presence

| Variable                 | P-value |
|--------------------------|---------|
| Notch presence           | 0.22    |
| Incipient notch presence | 0.39    |

Variables tested using Fisher's exact test, which are notch presence (p-value=0.22) and incipient notch presence (p-value= 0.39), did not show a significance difference in their presence. This means that notch presence and incipient notch presence were not significantly different between the cave roof fall assemblage and the hammerstone on anvil assemblage. FET p-values are summarized in Table 14.

#### *Spearman's rank correlation*

**Table 15** P-values and Correlation Coefficients From Spearman's Rank Order on Fragmnet Size Categories Between both Actors

| Fragment size (cm) | P-value | Rho coefficient |
|--------------------|---------|-----------------|
| Under 2            | 0.09915 | 0.4268647       |
| 2-2.99             | 0.4766  | 0.191865        |
| 3-3.99             | 0.6631  | 0.1181229       |
| 4-4.99             | 0.5408  | 0.1652486       |
| 5-5.99             | 0.7867  | 0.07350524      |
| 6-6.99             | 0.3672  | 0.2416661       |
| 7-7.99             | 0.7047  | -0.1028395      |
| 8-8.99             | 0.8744  | 0.04297722      |
| 9-9.99             | 0.8792  | -0.04134491     |
| Over 10            | 0.1293  | 0.3956787       |

Variables tested using Spearman's rank correlation were fragment size categories (see Table 8). Each fragment size variable was tested by investigating if a monotonic relationship

exists between fragment size categories produced by both actors. The p-value of all fragment size variables came back as not significant ( $p\text{-value} > 0.05$ ) as seen in Table 15. This indicates that a monotonic relationship does not exist in fragment categories created by both actors. The overall distribution of each actor's fragment size, in relation to the overall fragment count can be seen in Figure 48.

#### *Mann-Whitney U Test*

**Table 16** P-values for All Variables Tested Using the Mann-Whitney U Test

| Variable  | P-value   |
|---|-----------|
| Flake count   | 0.016*    |
| Pit count   | 0.0024*   |
| Groove count  | 0.10      |
| Striation count                                     | 0.13      |
| Distal epiphyseal element length (cm)               | 0.32      |
| Proximal epiphyseal element length (cm)             | 0.46      |
| Fragments with cortical surface                     | 0.73      |
| Fragments with pits and/or grooves                  | 0.073     |
| Percent cortical fragments with pits and/or grooves | 0.000094* |
| Pseudo-notch count                                  | 0.30      |
| Notch breadth to notch depth ratio                  | 0.26      |

Three variables of the eleven variables tested showed a significant difference as seen in Table 16. Significant variables are differentiated from insignificant variables by red and a star. Flake count ( $p\text{-value}=0.016$ ), pit count ( $p\text{-value}=0.002$ ), and percent cortical fragments with pits or grooves ( $p\text{-value}=0.00009$ ) were all variables that pointed towards a difference between cave roof fall from hammerstone-on-anvil percussion.

Eight variables were not significant in differentiating between cave roof fall and hammerstone-on-anvil percussion. The variables that are not significant are summarized in Table

16. Significant variables are differentiated from insignificant variables by red and a star. Most of the insignificant values have p-values above 0.1 which are all well outside of the necessary 0.05 threshold. One exception is fragments with pits and grooves which has a P-value of 0.073 which is close to threshold. This p-value might be due to the small sample size used in this experiment.

#### *Presence/absence*

Both assemblages had BSMs related to dynamic impact stress relief which are ribs and hackle marks (Fisher, 1995; Johnson, 1985). Ribs were observed on at least one fragment in each bone assemblage. Hackle marks were observed on at least one fragment in both bone assemblages. This indicates that dynamic impact was used as a causal agent by both actors to fracture the diaphysis (Gifford-Gonzalez, 1991). The results are summarized in Table 13.

#### *Untestable Variables*

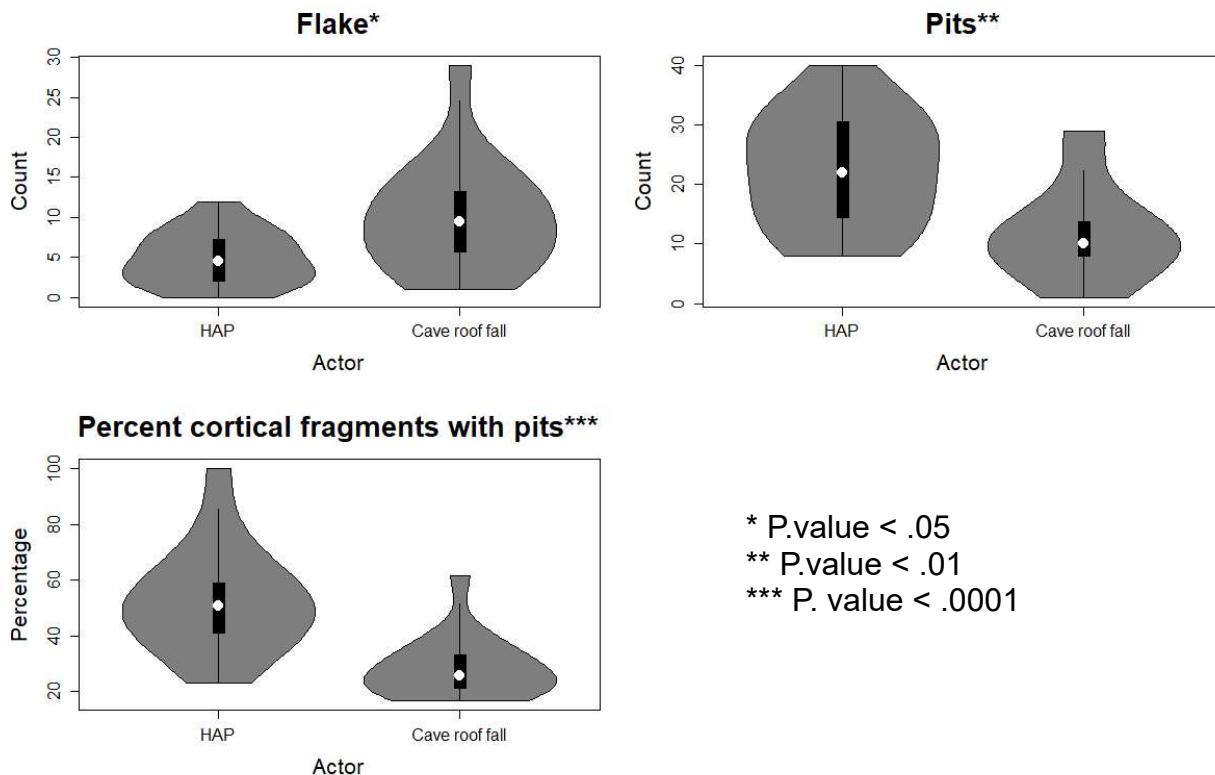

**Table 17** Variables That Could not be Tested or Were Not Designed to be Tested with Supporting Reasoning

| Variable                                | Reason   |
|---|--|
| Fragment count                          | No archaeological application                          |
| Fragments with notches                  |  |
| Percent cortical fragments with notches | Less than 5 observations in the cave roof fall sample. |
| Pseudo-notch to notch ratio             |  |
| Flake scar breadth to notch depth ratio |  |
| Release angle( $^{\circ}$ )             |  |
| Notch breadth                           | Not tested following Capaldo &                         |
| Maximum notch depth                     | Blumenschine (1994) methodology.                       |
| Flake scar breadth                      | Used to make ratios                                    |

Nine variables could not be tested or were not tested as seen in Table 17. Five of the variables could not be tested due to it having less than five observations, which is the minimum

number of observations necessary for the Mann-Whitney U test to test for a difference. Fragment count was not tested because it is sensitive to influence by other actors, making it not applicable to archaeological sites. Three variables were purposefully not tested and not included in Table 13. These variables are notch depth, notch breadth and flake scar breadth. They were used to create the ratios of notch breadth to notch depth and flake scar breadth to notch depth. Those three variables were not tested by Mann-Whitney U test or any other test as following Capaldo & Blumenschine (1994) methodology.

#### 4.4 Significant Variables

*Figure 49 Violin plots of all significant variables. P-value indicators present*

Figure 49 shows violin plots for all three significantly different variables. The violin plots do show that a difference exists between the two actors. This is indicated by the median (white

dot) of one actor or both actors existing outside of the interquartile range (black box). An overall difference can also be seen between the medians themselves.

#### *Flake count*

Flake count was one of the variables that was found to be significantly different between hammerstone-on-anvil percussion. The cave roof fall sample had a median of 9.5, while the hammerstone-on-anvil sample had a median of 4.5 which is half as small as seen in Table 13. This rejects the null hypothesis that there is no difference between the median of the two samples. This leaves the alternative hypothesis, that there is a difference in flake count. This difference between the medians is also seen in Figure 49. This can be reinterpreted as cave roof fall creates twice as many flakes than hammerstone-on-anvil percussion.

#### *Pit count*

Pit count was identified as a variable that was significantly different between cave roof fall and hammerstone-on-anvil percussion. This can be seen in the difference between the medians. The median of cave roof fall is 10 while the median of hammerstone-on-anvil percussion is 22 (see table 13). The hammerstone-on-anvil percussion median is almost twice as large as the cave roof fall median. This difference in medians rejects the null hypothesis. This leaves the alternative hypothesis, that the pit count in the two actors are different. This difference in medians is displayed in the violin plot in Figure 49.

#### *Percentage of cortical fragments with pits*

The percentage of cortical fragments with pits is the final variable that points towards a difference between cave roof fall and hammerstone-on-anvil percussion. The difference between the two samples can be seen in their medians and is illustrated in Figure 49. The cave roof fall median is approximated to 0.3, while the hammerstone-on-anvil percussion median is

approximated to 0.5 which is almost twice as large as illustrated in Table 13. This means that hammerstone-on-anvil percussion produces a higher percentage of fragments affected by pits and/or grooves. This difference in medians falsifies the null hypothesis. This leaves the alternative hypothesis, that there is a difference in the proportion of flakes with a pit and/or groove as the only hypothesis left.

#### **4.5 Non-Significant Variables**

The rest of the tested variables did not have a significant result for their appropriate tests, as seen in Table 14, 15 and 16. These variables can be grouped together under the following umbrella terms: fragmentation indicators, BSMs, fragment size, and ratios. The hypotheses put forward to test these variables are summarized in Table 10.

##### *Fragmentation indicators*

Fragmentation indicators encompass fragments with a cortical surface. Because the P-value provided by the Mann-Whitney test is above 0.05 as seen in Table 16, it can be inferred that there is no difference between both samples. The overlap between the medians can be seen as violin graphs in the Appendix. This falsifies the alternative hypothesis and leaves only the null hypothesis. This suggests that neither actor produces more fragments with an intact cortical surface than the other.

##### *BSM*

The BSM that were found to not be different are groove count, striation count, count of fragments with a pit or a groove, pseudo-notch count, notch, and incipient notch presence. The P-value of all these variables was above 0.05 as seen in Table 14 and 16. This implies that there is no significant difference between the medians of these variables for those tested using Mann-Whitney U test and that the binary response tested by FET is not different. This falsifies the

alternative hypotheses leaving only the null hypotheses. This can be interpreted as groove count, striation count, the count of fragments with a pit, pseudo-notch count, notch and incipient notch presence cannot be used to differentiate between the two actors, because neither actor produces more BSM than the other actor.

#### *Fragment size*

All fragment sizes proved to not be statistically significant including epiphyseal element length. All these variables had a P-value larger than 0.05 as seen in Table 15 and 16. This implies that there is no significant difference in medians for variables tested with Mann-Whitney U test and a monotonic relationship does not exists between fragment size for both actors. This falsifies the alternative hypothesis and leaves only the null hypothesis. Violin plots in the Appendix illustrate the overlap between medians for epiphyseal element length. The lack of a monotonic relationship between fragment size for each actor is seen in the scatter plots located in the Appendix. This means that fragment size variables and epiphyseal element lengths are not different or correlated between cave roof fall and hammerstone-on-anvil percussion.

#### *Ratios*

The only ratio that is part of this umbrella term is notch breadth to notch depth. The P-value, as seen in Table 16, is above 0.05 which means that there is no difference between the two sample medians. This falsifies alternative hypothesis and leaves only the null hypothesis. The overlap between the medians is visualized as a violin plot in the Appendix. The overlap between the medians means that notch breadth to notch depth is not different between the two actors because both create similarly sized notches.

## **4.6 Research Question Assessment**

Testing indicates that out of all variables tested, three proved to be different. With this information, the null hypothesis, that the taphonomic pattern of cave roof fall is not different from hammerstone-on-anvil percussion, can be falsified because three variables were significantly different. The first alternative hypothesis that all variables collected will be different between the two assemblages can also be falsified because only three variables out of the twenty three tested variables were found to be different. This leaves the second alternative hypothesis, that only some of the variables will be different between the two assemblages, as the only viable option. In turn this informs the research question. Yes, the taphonomic signature of cave roof fall is different from hammerstone-on-anvil percussion, but only when flakes, pits, and the proportion of fragments with pits are considered.

## **4.7 Summary**

This actualistic experiment produced three variables that are different between cave roof fall and hammerstone-on-anvil percussion. These variables are flake count, pit count, and the percentage of fragments with pits and/or pits. Cave roof fall creates a greater number of flakes than hammerstone-on anvil percussion. Hammerstone-on-anvil percussion creates more pits as cave roof fall. The percentage of fragments with pits and/or grooves likewise was larger in the hammerstone-on-anvil percussion sample than in the cave roof fall sample. These variables together inform the research question, that the taphonomic signature of cave roof fall is different from hammerstone on anvil percussion only when the significantly different variables are considered. The summary statistics for these statistically different variables are provided in Table 13 and visualized in Figure 49. The following chapter will discuss the implications of these variables and what possibly drives the difference seen in the median between both samples.

## CHAPTER V: DISCUSSION

### 5.1 Significantly Different Variables

As presented in the Results Chapter, three variables were found to be significantly different between the taphonomic pattern of cave roof fall and hammerstone-on-anvil percussion using a Mann-Whitney U test. The variables that had a significant difference in their medians are flake count, pit count, and percentage of fragments with pits. These variables are believed to be influenced by either the boulder impact force or the dual impact action of the hammerstone and anvil on the bone diaphysis. Variables that are impact force dependent seem to lean towards cave roof fall, while the variables other than these seem to be influenced by the dual impact action of the hammerstone-on-anvil percussion.

#### *Impact Force, Dual Impact Action, and Blow Distribution*

Impact force can be described as the force that an object transfers to another object at the time of impact. The impact force is usually transferred as energy into the receiving object. A higher impact force can be implied about each actor by referring to the number of blows needed to break the diaphysis as seen in Table 11 and 12. On average cave roof fall required about two blows to fracture the tibial diaphysis. This is significantly less when compared to the hammerstone-on-anvil average of 21.9. By comparing the number of blows needed to fracture the tibial diaphysis, it can be implied that cave roof fall produces a higher impact force than hammerstone-on-anvil percussion.

Blow distribution can be defined as the places along the diaphysis where the boulder or hammerstone contacted the bone surface during bone fragmentation. As seen in Table 11 and 12, cave roof fall had a small blow distribution along the diaphysis of the bone, on average delivering two blows. Hammerstone-on-anvil percussion had a much larger blow distribution, on

average requiring about twenty blows to fracture the diaphysis. While blow distribution does not influence any of the significant variables, it could influence some of the non-significant variables.

The dual impact action refers to the hammerstone and anvil impacting two separate sides of the bone diaphysis. Cave roof fall only impacts one side of the bone. This difference is based on the fracture mechanics employed by each actor. Cave roof fall impacted only the medial side of each bone. Hammerstone-on-anvil percussion required for the bone to be impacted from two sides, usually medial and lateral. While previous research has shown that blow intensity is not correlated to BSM production, it could be reasonably assumed that a two pronged assault on the diaphysis by hammerstone and anvil could produce more BSM than a unilateral assault seen in cave roof fall (Pickering & Egeland, 2006).

#### *Bone Flakes*

Bone flakes are traces created due to a stress response by the diaphysis following a loading episode (Johnson, 1985). This difference in medians seems to lean towards cave roof fall, as cave roof fall exhibits a higher median. This implies that a higher flake count is seen in the cave roof fall sample.

A possible explanation for the higher number of flakes created by cave roof fall is the higher impact force seen in cave roof fall. The falling boulder used in the cave roof fall simulations breaks the bone shaft through a massive blow concentrated on a small portion of the diaphysis. A high energy transfer is further amplified by a smaller surface area, as the energy can only dissipate at the point of impact and in the surrounding area leading to a higher energy distribution per bone surface area. This contrasts with how hammerstone-on-anvil fractures the diaphysis. Each hammerstone impact transfers less energy to the diaphysis than cave roof fall as

seen in table 11 and 12. Much like the energy transferred by the impact boulder is amplified by a small surface area, the hammerstone impact is also amplified by a small, affected surface area, but nowhere to the degree of the boulder impact. If the inference that cave roof fall does produce a higher energy transfer into the diaphysis can be made based on the impact data, then it can be assumed that more flakes will be produced by cave roof fall. This inference can be made because bone flakes are a stress relief response to energy transfer during a loading episode, so with a higher energy transfer, more flakes should be created (Johnson, 1985).

#### *Pits and percentage of fragments with pits*

Pits are created when the topographic relief of a rock's contact face imprints itself on the diaphysis of the bone (Blumenshine & Selvaggio, 1988). Mountains in this relief leave behind pits after each contact with the diaphysis. The number of pits observed in each sample and the percentage of fragments with pits have been shown to be different between cave roof fall and hammerstone-on-anvil percussion. While pits and the percentage of fragments with pits are two distinct variables, they will be discussed together because they are intimately connected. As indicated by the medians of both samples, the percussion pit count and percentage of fragments with percussion pits have much higher medians than those of impact pits and the percentage of fragments with impact pits. This suggests that hammerstone-on-anvil percussion produces more percussion pits and fragments with percussion pits than cave roof fall.

A possible driver for the difference in pit count and percentage of fragments with pits and/or grooves that is seen between the two assemblages is the way that each actor mechanically interacts with and fractures the diaphysis. Cave roof fall is a unidirectional application of force on the bone side that is pointing towards the cave roof. As a result, all BSM including pits and grooves will only occur on the impacted side of the bone. Hammerstone-on-anvil percussion in

contrast has a dual application of force from the hammerstone side and the anvil side. This means that hammerstone-on-anvil percussion has twice as many opportunities to imprint pits and grooves on the cortical surface of the bone (Blumenschine & Selvaggio, 1988). This difference in opportunities to imprint BSM on the bone surface could be a driving factor in pit expression. The percentage of fragments with pits too is likely influenced by the same driver, because pit expression and the proportion of fragments with pits are related. If more pits are created than the proportion of fragments that have a pit is likely to go up as well. While previous research has shown that there is no correlation between processing intensity (number of blows) and pit expression (Pickering & Egeland, 2006), however the dual impact of hammerstone-on-anvil versus the singular impact of roof fall could make a difference in the number of pits created. This is because hammerstone-on-anvil percussion affects both sides of the bone surface, while cave roof fall affects only one side of the bone, which in essence doubles the possible surface area that hammerstone-on-anvil percussion acts on.

## **5.2 Non-Significant Variables**

Twenty variables were found to be not significantly different between cave roof fall and hammerstone-on-anvil percussion. The lack of significance, however, can still be informative, about the suspected drivers and blind spots in experimental design. These variables have will be discussed in broad terms and have been grouped in the same variables that were presented in the Methods section.

*Visual*

### No magnification

Fragments that preserve cortical surface, notch count, incipient notch count, pseudo-notch count, fragments that preserve pits and grooves each proved to not be significantly

different. A common reason for the lack of significance could be attributed to the small sample size used in this experiment.

Fragments that preserve a cortical surface as a variable was not significantly different between the two actors. This suggests that one actor is not prone to stripping the cortical surface when compared to the other actor. This can be interpreted as the larger impact force associates with cave roof fall is able to remove just as much cortical bone as the dual attack of hammerstone-on-anvil percussion or vice versa.

Notches did not appear at a different rate in either assemblage. This is interesting because notches were predicted to appear more in the hammerstone-on-anvil sample, than the cave roof fall sample. This was predicted based on the dual impact action of the hammerstone and anvil affecting two sides of the bone increasing the chances that a notch will form. Animal size could be a different possible explanation, as suggested by Capaldo & Blumenshine (1994), where they found less notches on size 3 animals than size 1 and 2. The bison bones used in this experiment are size 4, which could dampen notch production regardless of impact force, or the dual impact action of hammerstone-on-anvil percussion. incipient notches did not appear at a different rate in the two assemblages.

Incipient notches appeared at the same rate in both assemblages. Cave roof fall was predicted to create more incipient notches because of more energy transfer and dissipation from the impact site. This was thought to create more incipient notches away from impact site, as the fracture front fails to penetrate the thickness of the bone. A possible explanation for this is either that cave roof fall does not dissipate enough energy to promote incipient notches, or that hammerstone-on-anvil percussion dissipates a similar amount of energy over the whole surface area of the bone.

Neither actor seems to have produced an overabundance of pseudo-notches compared to the other. This suggests that while pseudo-notches are seen as an incomplete stress relief trace, neither the energy generated impact force nor the dual impact action of the hammerstone and anvil seem to influence pseudo-notch count.

Finally, fragments that preserve pits and grooves were not shown to be different between the two actors. This is an interesting result when compared to pit count and the percentage of fragments with pits. This might suggest that both actors create fragments with pits at a similar rate, but differ in imprinting pits, and the proportion of fragments with pits. It should be noted that the p-value associated with fragments with pits (0.073) is close to the 0.05 threshold to be significantly different between the two actors. With a larger sample size this variables might prove to be different between the two actors.

### Magnification

Striation count and grooves count both proved to not be different between the actors. This is interesting because both were suspected to be higher in the cave roof fall sample. The controlled and methodological breakage technique seen in hammerstone-on-anvil percussion was suspected to dampen the expression of grooves and striations. Cave roof fall was projected to create more striations and grooves due to the random interaction between the diaphysis and the boulder coming to rest on the ground after the impact. This extra movement and contact with an abrasive surface were thought to produce more striations and pits. As indicated by the results this was not the case. It could be possible that while hammerstone-on-anvil percussion is done in a more methodological manner, anvil slippage and other unaccounted variables do enable the expression of grooves and striations. Likewise, it could be possible that the extra contact that the boulder has with the bone is not enough to promote the overexpression of grooves and striations.

Alternatively, a small sample size might have had a role to play in the lack of a significant difference observed in striation count and groove count. With a larger sample size, these two variables might be significantly different.

#### Presence/Absence

Ribs and hackle marks were present in at least one fragment in each bone assemblage. This does indicate that both actors fracture bone using dynamic loading as a causal agent, however, this does not help in differentiating between the two. If both actors fracture bones through dynamic loading, this means that a sample of bones fractured by cave roof fall cannot be distinguished from a sample of bones fractured through hammerstone-on-anvil percussion, based solely on the presence or absence of ribs and hackle marks, maintaining the equifinality between the two actors.

#### *Measured*

##### Fragment Size

All the fragment size categories proved to not have a monotonic relationship between actors. One possible explanation for the lack of a relationship between fragment size categories for each actor is sample size. The lack of sample size can be seen in the discrepancy between sample size and rho coefficient. This is not a statistical interpretation, rather its an illustration of the idea that adding more data to a correlation test makes the correlation coefficient stronger (Mangiafico, 2018). In Table 15 fragments under 2 cm and over 10 cm have the most data, smallest p-value (0.099 and 0.13) and the highest correlation coefficient (0.43 and 0.4). In contrast, fragments between 8-8.99 cm and 9-9.99 cm have the least data, highest p-values (0.874 and 0.879) and smallest correlation coefficient (0.043 and -0.04). This means that there is not enough data to identify a correlation, especially in the variables with the lowest correlation

coefficient (Mangiafico, 2018). With a larger data set some of the correlations between opposing actor fragment sizes could come to light.

### Epiphyseal elements lengths

Epiphyseal element lengths were found not to be different. This is interesting, because both variables, proximal element length, and distal element length, were suspected to be statistically different due to the random nature of boulder strikes. A possible explanation is that enough energy was transferred into the diaphysis by impact force during the cave roof fall experiments to fully fracture the diaphysis outside of the impact area and mimic the epiphyseal element lengths produced by hammerstone-on-anvil percussion. Another possibility might be that the overlap between epiphyseal lengths produced by cave roof fall and hammerstone-on-anvil percussion are an artifact of the small sample size. With a larger sample size, these two variables might prove to be different.

### *Ratios*

The only tested ratio, notch breadth to notch depth, proved not to be significant different between cave roof fall and hammerstone-on-anvil percussion. This ratio describes the overall shape of the notch. It is likely that loading type and animal size category contributed to the lack of a significant difference. As indicated in Capaldo & Blumenschine (1994) with size 3 animals notch breadth to notch depth can no longer distinguish between carnivore created notches and hammerstone-on-anvil percussion created notches. Since buffalos are considered size 4 it can be inferred that differences in notch shape between cave roof fall and hammerstone-on-anvil percussion would be minimized (Blumenschine, 1986). Another possibility might be that the same loading mechanism, in this case, dynamic loading, creates similar or indistinguishable notches (Johnson, 1985). A third possibility might be that an overlap in notch shape is an artifact

of the small sample size. With a larger sample size, notch shape might be a statistically different variable.

### **5.3 Archaeological Implications**

Flake count, pit count and proportion of fragments with pits and/or grooves were the variables that were different between actors. From those variables it can be inferred that the taphonomic signature of cave roof fall is one with more flakes (higher median) and less pits and proportions of fragments with a pit and/or groove (smaller median), when compared to hammerstone-on-anvil percussion. The data gathered from these two single actor assemblages is not applicable to a multi-actor assemblage. This would be an assemblage where both hominins and cave roof fall modified the bones present. The lack of applicability is because while counts and proportions were calculated on the segregated assemblages a pit for example could not be attributed to one actor or the other without prior knowledge of where the pit came from. There were no reliable qualifying or quantifying criteria to accurately differentiate an impact pit from a percussion pit or an impact flake from a percussion flake without prior knowledge of its provenience. This means that these variables are not viable to be applied to a multi-actor archaeological assemblage, which are the most common type of assemblage (Gifford-Gonzalez, 1991).

The lack of criteria to reliably link BSM and the responsible actor is not the only problem with using those variables. Other processes can modify the expression of these variables within an archaeological setting. For example, pits can be abraded away by rough surfaces like sand (Fisher, 1995). This might cause a hammerstone-on-anvil made assemblage to look like a cave roof fall modified assemblage by decreasing the number of observable pits. Flakes are subject to the same attritional forces that can alter other types of assemblages (Gifford-Gonzalez, 2018c). A

cave roof fall created assemblage can resemble a hominin modified assemblage if flakes are deleted through trampling, weathering, or transport. The high potential for additional taphonomic forces to interact with assemblages makes even the significant variables found during this actualistic experiment less conducive determining roof fall as an actor.

This experiment has shown that cave roof fall and hammerstone-on-anvil percussion operate through the same causal agent (dynamic loading) and effector (a rock impact to the bone diaphysis). Furthermore, both actors produce the same traces as seen in the bone flakes, pits, grooves, striations, notches, incipient notches, and pseudo-notches collected from both assemblages. These traces do occur in different counts and frequencies as illustrated by this experiment, but the traces themselves are indistinguishable from a qualitative descriptive approach. This implies that within a hominin modified cave assemblage, cave roof fall would simply amplify the hominin signature adding more of the same BSMs to the assemblage.

Identification of cave roof fall as the definitive actor can only be achieved if the assaulting debris is found on top of the afflicted bone as seen at Shanidar cave (Solecki, 1957; Trinkaus, 1983). However, there are cases as seen in this experiment where boulder 1 broke on impact. A similar situation can be applied to cave sites, where a bedrock fragment breaks on impact with a bone, fractures it imprinting BSMs on the bone surface and vanishing from the archaeological record through erosion. This scenario can influence the way that assemblages believed to be hominin modified are evaluated. For example, a small hominin modified assemblage can be exaggerated if bones are covertly added by cave roof fall, distorting the interpreted size and function of a site. A more extreme example is if cave roof fall modifies hominin bones that were defleshed as part of a mortuary practice and left on the cave floor. The regulated climate of the cave would increase the time that defleshed bone would remain fresh.

The extended period of freshness increases the chance that green, defleshed bones are impacted by falling debris. In this instance, hominin modified bones with cutmarks would further be modified by traces associated with dynamic loading by a falling bedrock boulder. This could happen multiple times on different bones, in different time periods. The interpretation of this assemblage would likely be that the hominin bones were processed for their nutritional value. The error of this interpretation is evident in a laboratory experiment but much more difficult to interpret in a practical capacity. These types of interpretation has been made at sites like Krapina Cave that have a suspected cave roof fall component (Mann & Monge, 2006; Trinkaus, 1985; Ullrich, 2005)

To summarize the variables that proved to be significantly different in this experiment are not applicable to the archaeological record. The lack of archaeological application is because while counts and frequencies were created around each trace, the traces themselves did not have any reliable distinguishing properties. This is problematic in a multi-actor assemblage, because of traces themselves cannot be distinguished between percussion and cave roof fall derived, then all the distinguishing criteria at higher levels, that were investigated in this experiment are fraught with errors. The lack of distinction can also be applied to archaeological sites with a suspected roof fall component. The lack of a proper trace actor connection can greatly distort the interpretation of an assemblage. A large sample size might yield better indicators, such as quantifiable notch dimensions proposed by Capaldo & Blumenschine (1994). A different approach would be to quantify BSM dimensions using a profilometer as proposed by Pante et al. (2017).

## **5.4 Limitations of the study**

This study was the first step in characterizing the taphonomic pattern of cave roof fall. However, there are certain limitation which should be considered. The pulley system that was used to simulate cave roof fall had some inherent flaws. The sample size and animal size category used for this study do have some flaws. Finally, the untested variables are a reminder that this study does have some limitations in its interpretations.

### *Pulley Design*

Cave roof fall was simulated by looping a rope around two different tree branches to achieve the intended heights. This simple design was used to avoid the rental of machinery which would overcomplicate the experiment through higher expenses, scheduling, and proper certifications. This pulley design however had its draw backs. The first one was human error, as there were many times when the rock was slowed down either by mistakenly stepping on the rope, or through other human errors. The other draw back was friction. This was evident in the second part of the experiments where the rope would enter grooves or notches in the tree bark and slow down descent of the rock to a crawl. These incidents were recorded, but nothing could be done to rectify them.

### *Sample Size*

Sample size was a severe limitation in this study. This limitation was in part due to the supply of tibiae available as High Point Bison (the supplier) only slaughters a set number of bison during the spring and fall, this means that a limited number of tibiae were available. While sixteen bones are a good starting number, it should be a priority to expand this number in future.

### *Animal Size Class*

Bison as a size 4 animal might also have been a limitation (Blumenschine, 1986). As indicated in Capaldo & Blumenschine (1994) notch frequency and diagnostic notch properties diminish when going from a size 2 animal bone to a size 3 animal bone. With this trend it is entirely possible that a size 4 animal bone might not harbor as many diagnostic variables, as say a size 2 animal bone might harbor.

### *Untested Variables*

Most of the variables related to notches were untestable due to fewer than 5 observations in the cave roof fall sample. These notch-related variables were fragments that exhibit a notch, percentage of fragments with a notch, pseudo-notch to notch ratio, flake scar breadth to notch depth and release angle. With a higher sample size these variables might be able to be tested to ascertain their significance potential. Of the untested notch variables, it is likely that overall flake dimension would not be different due to the use of a size 4 animal and the similarity is used causal agent (Capaldo & Blumenschine, 1994).

## **5.5 Summary**

Impact force, dual impact action by the hammerstone and anvil and blow distribution are suspected to be the drivers behind the statistically different variables flake count, pit count and percentage of fragments with pits. Impact force seems to be the driver for cave roof fall influenced variables, while the dual impact action by the hammerstone and anvil, and blow distribution seems to be the driver for hammerstone-on-anvil influenced variables. All the other tested variables are either inherently not different or are not significantly different due to a small sample size. These variables are not useful in an archaeological setting because the traces themselves are not identifiable. Future attempts should focus on a quantifiable approach to

describe and differentiate the traces produced by both actors. The study has some limitation in boulder drop mechanism, sample size, animal size category and untested variables due to a small sample size. These limitations should be considered for any future studies.

## CHAPTER VI: CONCLUSION

### 6.1 The Experiment

The purpose of this experiment was to characterize the taphonomic signature of cave roof fall and compare it to the taphonomic signature of hammerstone-on-anvil percussion. This was done to solve the current equifinality that exists between the two actors (Oliver, 1989). This equifinality exists because both actors leave the same basic traces, fracture the diaphysis through the same causal agent and have the same effector. Before a comparison between the two actors could be made, actualistic experiments were carried out to create a sample for each actor following the suggestion of Binford (1981b). The hammerstone-on-anvil sample was created by placing a bone on an anvil and hitting the diaphysis longitudinally with a hammerstone. The cave roof fall sample was generated by simulating a cave roof fall from various heights and with various weights over bones. To explore the current equifinality, the traces of both actors were described, quantified and compared.

Thirty-four variables were created to categorize the data gathered from the traces. These variables were organized by the method with which they were gathered. Visually gathered variables were identified by an unaided visual inspection, aided visual inspection using a 3x magnifying glass and a 10x hand lens, or most simplistically by their presence or absence. Measured variables were measured using digital calipers or a tape measure. Composite variables were ratios that were constructed using either visual data or measured data. The same variables were gathered from both the hammerstone-on-anvil and the simulated roof fall assemblages. Notch and incipient notch presence was tested using FET. Fragment size categories were tested for a monotonic correlation using Spearman's rank order test. All other testable variables were tested using a Mann-Whitney U test to test for a difference. Presence/absence variables were

counted and recoded as a percentage. Nine variables were not tested. Eight of these variables could not be tested, as seen with the notch measurements (Capaldo & Blumenschine, 1994), or had less than five observations in the cave roof fall sample, as illustrated by most of the data pertaining to notches. Fragment count was not tested because it can easily be influenced by other actors and is not taphonomically informative.

Three variables were shown to be significant different between cave roof fall and hammerstone-on-anvil percussion. The three significant variables were flake count, pits count, and percentage of cortical fragments with pits. Twenty variables proved not be significantly different between cave roof fall and hammerstone-on-anvil percussion. These results suggest that there is a difference between the taphonomic signature of cave roof fall and hammerstone-on-anvil percussion.

The variables that proved to be significant are most likely influenced by impact force and the dual impact of the hammerstone and anvil. A higher number of flakes seem to be driven by the higher impact force generated by cave roof fall. Higher pit count, percentage of fragments with pits are likely influenced by the dual impact of the hammerstone and anvil acting on both sides of the bone. Other variables might prove significant if the sample size is increased and more observations are recorded. The archaeological potential of the significantly different variables is called into question however, because the lack of differentiation at the trace level makes the identification of traces in a complex multi-actor assemblage unattainable.

## 6.2 Future Directions

This experiment characterized the taphonomic signature of cave roof fall by analyzing the trace patterns leftover from an actualistic simulation of cave roof fall. This data was compared to data collected from an actualistically derived hammerstone-on-anvil sample, which yielded some

significantly different variables. However, the sample size was small, with only sixteen bones in each sample. Some variables were not able to be tested because not enough observations were recorded. Future research needs to expand the cave roof fall sample size. Furthermore, the different variables need to be verified after the sample size has been expanded to validate that the variables are still different and not an artifact of the small sample size. Finally, with an expanded sample size, the variables that could not be tested need to be reanalyzed to find their significance potential. A future study is recommended to investigate the two assemblages through quantitative means to effectively identify and characterize the two assemblages at a trace level.

The findings of this experiment are the first steps toward investigating and defining the taphonomic pattern of cave roof fall. If the statistically different variables do survive the verification process, then the taphonomic signature seen in this experiment can be connected to cave roof fall only within an actualistic setting. However, the significant variables cannot be applied to the archaeological record because the traces that the variables are built upon are not descriptively unique and cannot be differentiated between actors. Future research should describe the traces created by both actors through quantifiable means. A qualitative approach to explore the equifinality between the two actors failed to do so, however a future quantitative approach might provide the means to refine the hominin taphonomic signature by potentially eliminating any interference caused by cave roof fall.

## APPENDIX

### Appendix 1: Materials

**Table 18** Materials used in Cave Roof Fall and Percussion Actualistic Studies

| Material                       | Type                               | Quantity          | Use   | Notes  |
|--------------------------------|------------------------------------|-------------------|---|--|
| Bison bone <sup>d</sup>        | Tibia                              | 16                | To be broken  | Defleshed  |
| Bison bone <sup>a</sup>        | Tibia                              | 16                | Percussion sample                                     | Bones were broken in a different experiment                            |
| Sandstone boulder <sup>b</sup> | 6.8 kilograms<br>13.6 kilograms    | 2<br>2            | To be dropped on bones                                | Duplicates bought in case one breaks                                   |
| Rope                           | 30.5 meters                        | 1                 | To hoist boulder up                                   |  |
| Heights                        | 4.6 meters<br>7.6 meters           | 1<br>1            | For boulder to be hoisted up to                       | Achieved using tree branches   |
| Tarp                           | Generic                            | 1                 | Prevent the loss of fragments                         |  |

| Permanent marker             | Black            | 2    | Accessioning                         | Fine point                                     |
| Plastic bags                 | Generic          | 32   | Fragments storage                    | Zip top  |
| Magnifying glass & Hand lens | 3x & 10x         | 1    | Identify BSM                         |  |
| Lamp                         | Incandescent     | 1    | Provide light for BSM identification |  |
| Putty                        | Impressive Putty | 9 oz | To create a mold of notches          | Reusable putty was used to bring down the cost |
| Goniometer                   | Generic          | 1    | To measure release angle             |  |
| Digital Calibers             | Generic          | 1    | To measure notch molds and fragments |  |
| R studio                     | Program          | N/A  | Statistical software                 | Vioplot package used                           |

<sup>a</sup>- Bison tibiae were procured from High Point Bison Ranch, Wyoming  
<sup>b</sup>-Sandstone boulder was donated by Rock Garden, Fort Collins, and Pioneer Landscaping, Fort Collins

## Appendix 2: Cave Roof Fall Raw Data Tables

**Table 19** 7.6 m Boulder Drops

| Bone Number | Bone Side | Impact Plane         | Rock (boulder) | Number of contacts before breakage occurred | Number of trials before breakage occurred |
|-------------|-----------|----------------------|----------------|---|---|
| 1           | Left      | Medial               | 2 (13.6 kg)    | 1   | 1   |
| 2           | Right     | Medial               | 2 (13.6 kg)    | 1   | 1   |
| 3           | Right     | Medial               | 2 (13.6 kg)    | 2   | 2   |
| 4           | Left      | Medial               | 2 (13.6 kg)    | 1   | 1   |
| 5           | Left      | Lateral <sup>^</sup> | 1*/3 (6.8 kg)  | 2   | 3   |
| 6           | Right     | Medial               | 3 (6.8 kg)     | 1   | 1   |
| 7           | Left      | Medial               | 3 (6.8 kg)     | 1   | 1   |
| 8           | Right     | Medial               | 3 (6.8 kg)     | 1   | 3   |

^Lateral side used due to the presence of cut marks from the butcher on the medial side  
 \*Rock(boulder) #1 only used for one drop because it broke upon impact. Rock #3 used for remainder of experiment

**Table 20** 4.6 m Boulder Drops

| Bone Number | Bone Side | Impact Plane | Rock (boulder) | Number of contacts before breakage occurred | Number of trials before breakage occurred |
|-------------|-----------|--------------|----------------|---|---|
| 9           | Right     | Medial       | 3 (6.8 kg)     | 1   | 1   |
| 10          | Left      | Medial       | 3 (6.8 kg)     | 3   | 4   |
| 11          | Right     | Medial       | 3 (6.8 kg)     | 1   | 1   |
| 12          | Right     | Medial       | 3 (6.8 kg)     | 2   | 2   |
| 13          | Right     | Medial       | 2 (13.6 kg)    | 3   | 3   |
| 14          | Left      | Medial       | 2 (13.6 kg)    | 1   | 1   |
| 15          | Left      | Medial       | 2 (13.6 kg)    | 4   | 4   |
| 16          | Right     | Medial       | 2 (13.6 kg)    | 3   | 3   |

**Table 21** Raw Data from the Roof Fall Simulation Experiment Trials

| Bone     | Trial | Trail Results  | Drop Height | Rock Number | Rock Weight |  |
|----------|-------|--|-------------|-------------|-------------|--|
| ASH-T-01 | 1     | Contact with bone. Breakage occurred.                        | 7.6 Meters  | Boulder 2   | 13.6 KG     |  |
| ASH-T-02 | 1     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-03 | 1     | Contact with bone. No breakage.                              |             |             |             |  |
| ASH-T-03 | 2     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-04 | 1     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-05 | 1     | Contact with bone. No bone breakage. Rock breakage occurred. |             | Boulder 1   | 6.8 KG      |  |
| ASH-T-05 | 2     | No contact   |             | Boulder 3   |             |  |
| ASH-T-05 | 3     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-06 | 1     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-07 | 1     | Contact with bone. Breakage occurred.                        | 4.6 Meters  | Boulder 3   | 6.8 KG      |  |
| ASH-T-08 | 1     | No contact.  |             |             |             |  |
| ASH-T-08 | 2     | No contact.  |             |             |             |  |
| ASH-T-08 | 3     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-09 | 1     | Contact with bone. Breakage occurred.                        |             | Boulder 3   | 6.8 KG      |  |
| ASH-T-10 | 1     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-10 | 2     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-10 | 3     | No contact with bone.  |             |             |             |  |
| ASH-T-10 | 4     | Contact with bone. Breakage occurred.                        | 4.6 Meters  | Boulder 2   | 13.6 KG     |  |
| ASH-T-11 | 1     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-12 | 1     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-12 | 2     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-13 | 1     | Contact with bone. Breakage did not occur.                   |             | Boulder 2   | 13.6 KG     |  |
| ASH-T-13 | 2     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-13 | 3     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-14 | 1     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-15 | 1     | Contact with bone. Breakage did not occur.                   | 4.6 Meters  | Boulder 2   | 13.6 KG     |  |
| ASH-T-15 | 2     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-15 | 3     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-15 | 4     | Contact with bone. Breakage occurred.                        |             |             |             |  |
| ASH-T-16 | 1     | Contact with bone. Breakage did not occur.                   | 4.6 Meters  | Boulder 2   | 13.6 KG     |  |
| ASH-T-16 | 2     | Contact with bone. Breakage did not occur.                   |             |             |             |  |
| ASH-T-16 | 3     | Contact with bone. Breakage occurred.                        |             |             |             |  |

**Table 22** Raw Cave Roof Fall and Hammerstone-on-Anvil Percussion Collected from All Fractured Bison Bones
